ABSTRACT
This paper discusses our participation in INEX (the Initiative for the Evaluation of XML Retrieval) using the TIJAH XML-IR system. TIJAH's system design follows a 'standard' layered database architecture, carefully separating the conceptual, logical and physical levels. At the conceptual level, we classify the INEX XPath-based query expressions into three different query patterns. For each pattern, we present its mapping into a query execution strategy. The logical layer exploits probabilistic region algebra as the basis for query processing. We discuss the region operators used to select and manipulate XML document components. The logical algebra expressions are mapped into efficient relational algebra expressions over a physical representation of the XML document collection using the 'pre-post numbering scheme'. The paper concludes with a preliminary analysis of the evaluation results of the submitted runs.

1. INTRODUCTION
This paper describes our research for INEX 2003 (the Initiative for the Evaluation of XML Retrieval). We participated with the TIJAH XML-IR retrieval system, a research prototype built on top of the MonetDB database kernel [1]. Key feature of the TIJAH system is its layered design, following the basic system architecture of relational database management systems.

Traditional information retrieval systems represent a document as a 'bag-of-words'. Inverted file structures provide the basis for implementing a retrieval system for such 'flat' documents. In the case of structured documents however, we think designing the retrieval system following 'the database approach' is best to keep the more complex data representation manageable.

The main characteristic of the database approach is a strong separation between conceptual, logical and physical levels, and the usage of different data models and query languages at each of those levels [20]. In relational database systems, a significant benefit of this data abstraction (through the separation between the levels in database design) is to enable query optimization. A SQL query (a 'calculus expression') at the conceptual level is first translated into relational algebra. The algebraic version used at the logical level is then rewritten by the query optimizer into an efficient physical query plan. The physical algebra exploits techniques like hashing and sorting to improve efficiency [8].

For XML-IR systems, following this separation in layers gives another, additional advantage: by choosing the appropriate level of abstraction for the logical level, the development of probabilistic techniques handling structural information is simplified, and kept orthogonal to the rest of the system design. Section 3 details our approach, based on a probabilistic extension of text region algebras.

The paper is organized along the layers of the TIJAH system design. The following Section describes the query language used at the conceptual level, identifies three patterns in the INEX topic set, and explains how the language modeling approach to information retrieval is used for the about operator. Section 3 presents a probabilistic region algebra for expressing the three query patterns. Section 4 explains how the algebraic expressions are mapped into efficient relational algebra expressions over a physical representation of the XML document collection using the 'pre-post numbering scheme'. We conclude with a discussion of the experiments performed with our approach for the three INEX search tasks.

2. CONCEPTUAL LEVEL
For the conceptual level, we used the INEX query language as proposed by the INEX Initiative in 2002. The INEX query language extends XPath with a special about function, ranking XML elements by their estimated relevance to a textual query. As such, the invocation of the about function can be regarded as the instantiation of a retrieval model.

The retrieval model used for the about function is essentially the same as that used at INEX 2002 [12, 14]. We calculate the probability of complete relevance of a document component, assuming independence between the probability of relevance on exhaustivity and the probability of relevance on specificity.

The probability of relevance on exhaustivity, \( P(R_E) \), is estimated using the language modeling approach to information retrieval [11]. Instead of document frequency, we have used collection frequencies for the background model. The probability of relevance on specificity, \( P(R_S) \), is assumed to be directly related to the component length (following a log-normal distribution). Its steep slope at the start discounts the likelihood that very short document components are relevant. Its long tail reflects that we do not expect long document components to be focused on the topic of request.
The language model as used by our system disregards structure within a document component, i.e., the model treats a document component as a ‘flat-text’ document. This model property, and an informal inspection of the INEX 2003 topic list, led us to use only a subset of possible location step axes within an about function call; we only used the descendant-or-self::qname location step axis. Allowing other axes, like sibling::qname or following::qname requires correct probabilistic modeling for estimating probabilities in the language model, which our model did not offer at the time of evaluation.

Table 1: SCAS and VCAS pattern set. Note that xp1, xp2, axp1, axp2 and axp3 are location steps, and ‘/p’ denotes any set of terms or phrases to search for.

<table>
<thead>
<tr>
<th>Pattern</th>
<th>Pattern definition</th>

</tr>
<tr>
<td>$P_3$</td>
<td>$\text{xp[about(axp1, 't1/p1') \ OR \ about(axp2, 't2/p2')]}$</td>
</tr>
</tbody>
</table>

Since we did not have an automatic query processing facility, we processed the queries manually but in a mechanic fashion. Processing the INEX query patterns takes place in two steps:

- classify the query into a (sequence of) three basic query patterns (shown in Table 1);
- create a query plan to process the queries. The query patterns are visualized in Figure 1.

The basic pattern for all XPath based queries is the single location step, as defined in [7], augmented with an about function call (pattern $P_1$ in Table 1). When referring to, for example $xp_1$, we refer to the node-set representing the location step $xp_1$; in other words, a path leading to a certain location (or node) in the XML syntax tree. The first query pattern consists of one location step to identify the nodes to be retrieved, ranked by an about expression over a node-set reached by a second location step. The two other (more complex) patterns $P_2$ and $P_3$ are essentially multiple interrelated instances of the basic pattern $P_1$. The XPath location steps may also apply (Boolean) predicate filters, e.g. selecting nodes with a particular value range for $yr$.

### 3. LOGICAL LEVEL

The logical level is based on a probabilistic region algebra. Region algebra was introduced by Burkowski [2], Clarke et al. [3], and Tova and Milo [4]. The aim of the earliest text region algebra approaches has been to enable structured text search. Later, it has been applied to related tasks as well, including search on nested text regions [13], processing of structured text [17], and ranked retrieval from structured text documents [15].

The basic idea behind region algebra approaches is the representation of text documents as a set of ‘extents’, where each extent is defined by its starting and ending position. The application of the idea of text extents to XML documents is straightforward. If we regard each XML document instance as a linearized string or a set of tokens (including the document text itself), each component can then be considered as a text region or a contiguous subset of the entire linearized string. Therefore, a text region $r$ can be identified by its starting point $s_r$ and ending point $e_r$ within the entire linearized string. Figure 2 visualizes an example XML document (as a syntax tree) with the start point and end point numbering for the nodes or regions in the tree. As an example, the bdy-region corresponds to (closed) interval $[5..24]$.

Let us introduce the basic set of region operators. We use capital letters ($A$, $B$, $C$) to denote the region sets, and their corresponding non-capi tals to denote regions in these region sets ($a$, $b$, $c$). The operators take region sets as input and give a result which is again a region set. The definition of region operators is given in Table 2. Interval operator $I(t)$ returns the region set representing the occurrences of term $t$ as a content word in the XML document; note that it gives a result set in which $s_e = e_a$ for every region, assuming $t$ is a single term and not a phrase. Location operator $L(xp)$ denotes the sequential application of XPath location steps, i.e., axis- and node-tests (a definition of axis- and node-tests can be found in [16]). Optionally, location step operator $L$ also processes predicate tests on node or attribute values specified in the XPath expression.

<table>
<thead>
<tr>
<th>Operator</th>

<td>${a</td>
</tr>
<tr>
<td>$A \cap B$</td>
<td>${a</td>
</tr>
<tr>
<td>$A \cup B$</td>
<td>${a</td>
</tr>
</tbody>
</table>

Table 3 expresses the patterns identified in the previous Section using region algebra operators (ignoring ranking for either.

The basic idea behind region algebra approaches is the representation of text documents as a set of ‘extents’, where
now). Pattern 1 distinguishes between term (\(t\)) and phrase expressions (\(p = \{t_1, t_2, \ldots, t_n\}\)). Patterns 2 and 3 are rewritten into several interrelated instances of pattern 1. Table 4 introduces a probabilistic extension of the pure region algebra operators. In order to introduce ranking, we extend the notion of region with its relevance score; i.e., every region \(a\) has an associated relevance score \(p_a\). In cases where pure region algebra operators are used, the value of the introduced relevance score is equal to a predefined default value (e.g., \(p_a = 1\)) for each resulting region in a region set.

Table 5 gives the probabilistic region algebra expressions corresponding to the INEX query patterns identified before. The \(tp1\) is used to denote \(t'p/p'1\) or the combination of \(t'p/p'1\) and \(t'2/p'2\) (the choice between these options is made at the conceptual level). Similarly, \(tp2\) is either \(t'2/p'2\) or a combination of \(t'2/p'2\) and \(t'1/p'1\).

Expressing query plans using the operators given in Table 4 preserves data independence between the logical and the physical level of a database. Similarly, these operators enable the separation between the structural query processing and the underlying probabilistic model used for ranked retrieval: a design property termed content independence in [6]. The instantiation of these probabilistic operators is implementation dependent and does not influence the global system architecture. This gives us the opportunity to change the probabilistic model used or to modify the existing model while keeping the system framework, creating the opportunity to compare different probabilistic models with minimal implementation effort.

4. PHYSICAL LEVEL

The physical level of the TIJAH system relies on the MoneDB binary relational database kernel [1]. This Section details implementation and execution strategy for each of the patterns.

The text extents used at the logical level are represented by XML text regions at the physical level, and encoded using a preorder/postorder tree encoding scheme, following [9, 10]. The XML text regions are stored as three-tuples \(\{s_i, e_i, t_i\}\) for each XML region \(i\), where:

- \(s_i\) and \(e_i\) represent the start and end positions of XML region \(i\);
- \(t_i\) is the (XML) tag of each region.

The set of all XML region tuples is named the node index \(N\). Index terms present in the XML documents are stored in a separate relation called the word index \(W\). Index terms are considered text regions as well, but physically the term identifier is re-used as both start and end position to reduce memory usage. The physical layer has been extended with the text region operators shown in Table 6. Boolean predicate filters are always applied first. For further details on this indexing scheme, refer to [5, 14].

4.1 Pattern 1

Pattern 1 for VCAS Processing pattern 1 in Table 1 requires two basic steps: relating node-sets \(xp\) and \(axp\) to each other, and processing the \(about\) operator. Nodesets \(xp\) and \(axp\) must have a parent - descendant\(^1\) structural relation.\(^1\)Parent - child relationships are considered a specific variant of parent - descendant relationships.

Figure 3: Physical query plan for pattern 1.
ship. So, the pattern is processed as follows (visualized in Figure 3):

- Determine the correct axp node-set for ranking. On the physical level, this is done by executing a containment join between the node-sets xp and axp: axp ⊆xp. The result of this containment join is cxp or the set of those nodes of axp which are contained within nodes in xp;
- Perform the about operation on the nodes in cxp (the combination of ⊇ and Δ operators on the logical level);
- Return the ranking for the xp node-set, based on the rankings of the nodes present in cxp. Note that it is possible that the ranking returns a ranking for multiple axp descendant nodes for a single xp node (for example, multiple sections within an article). In that case, we take the average as the final score for the xp node in question. This step is the physical equivalent of the logical ⊇ (one descendant of the type of axp) or logical ⊉ (multiple descendants of the type of axp) operator.

**Pattern 1 for SCAS** The processing of pattern 1 for the SCAS run does not differ from the processing performed for the VCAS run. The containment join will automatically remove those xp nodes not containing one or more axp nodes. This ensures only the ‘correct’ axp nodes, those within a node from the xp node-set, will be ranked.

**4.2 Pattern 2**

**Pattern 2 for VCAS** For the processing of pattern 2 for the VCAS scenario, we assume that conjunctions and disjunctions specified in the query relate to the structure, and never to the query terms. In case node-sets axp1 and axp2 are equal, the pattern is rewritten to a pattern 1. If the node-sets axp1 and axp2 are not equal, it is possible that the node-sets represent completely different parts of the (sub)tree below xp, as depicted in Figure 1. In path-based terms, if the (sub)tree starting at xp does not contain both paths axp1 and axp2, that xp tree cannot be relevant for the strict scenario.

However, for a more vague query scenario, we argue that the absence of a descendant node does not render the requested (ancestor) target node irrelevant completely. Consider the following expression:

```xml
/article[
  about(./abstract, 'information retrieval')
  AND about(./section, 'XML data')
]
```

If an article contains no abstract, but it does score on ‘XML data’ in one or more of the sections, the question is whether the article is completely irrelevant. For a vague retrieval scenario this might not be the case. Therefore, we decided to process these expression types as follows. We split up the expression into a series of pattern 1 expressions, and combine the results of the individual pattern 1 executions. The example above is split up into the following two pattern 1 expressions:

- /article[about(./abs, 'information retrieval XML data')] - /article[about(./sec, 'information retrieval XML data')]

Both subpatterns are processed as pattern 1. The two resulting node-sets need to be combined for a final ranking. An intuitive combination function for the Δ operator is taking the minimum of the (non-zero) descendant scores, and for the ∇ operator the maximum. Note that, alternatively, a more formal probabilistic choice would be to use product and sum instead of minimum and maximum; whether this yields better results is an open question for further research.

**Pattern 2 for SCAS** For the SCAS scenario, all of the descendant nodes present in axp1 and axp2 need to be present in the context of an xp node. In path-based terms: if the path xp does not contain both a path axp1 and a path axp2, the path xp cannot be relevant. We filter out those xp paths, not containing both the axp1 and axp2 paths. This additional filtering step and the choice of operator to implement the complex ‘and’ (Δ) and ‘or’ (∇) operators define together the difference between strict and vague scenarios.

**4.3 Pattern 3**

**Pattern 3 for VCAS** Pattern 3 can be processed like pattern 2, except for the fact that the target element now lies deeper in the tree. We process this pattern by first splitting it up into multiple instances of pattern 1:

- xp[about(axp1, 't1/p1 t2/p2')]
- xp/xp2[about(axp2, 't1/p1 t2/p2')]

The pattern 1 execution already provides for aggregation of scores of a set of nodes of the same type, within a target element. The question remains however how to combine the scores of the nodes present in node-sets /xp/axp1 and /xp/xp2/axp2. Like before, these node-sets can represent nodes in completely different parts of the (sub)tree.

Based on the observation that the user explicitly asks for the nodes present in the /xp/xp2 node-set, we decided to use the rankings of those nodes as the final rankings. The first about predicate reduces node-set xp to those nodes for which a path axp1 exists. For the vague scenario however, we argue that absence or presence of axp1 does not really influence target element relevance (similar to pattern 2 in subsection 4.2).

Summarizing, the first about predicate in the pattern mentioned at the start of this subsection is dropped, rewriting the resulting pattern to a pattern 1 instance:

```xml
/xp/xp2[about(axp2, 't1/p1 t2/p2')]
```

This results in the following execution strategy for pattern 3 under the VCAS scenario: remove all about predicates from all location steps, except for the about predicate on the target element.

**Pattern 3 for SCAS** The processing of pattern 3 for the SCAS scenario is stricter in the sense that we can not simply
drop intermediate *about* predicates, as we did for the VCAS scenario. The general procedure consists of:

- splitting up the pattern into separate location steps;
- structural correlation of the resulting node-sets of each location step.

The target elements are ranked by their corresponding *about* predicate only; thus, ignoring the scores produced for the other *about* clauses in the query. Like in pattern 1, the target element can have multiple descendants; in that case, the descendants’ scores are averaged to produce the target element scores.

As an example, consider the following expression:

```xml
<article[about(./abstract, 't1/p1')]  
  //section[about(./header, 't2/p2')]  
  //p[about(., 't3/p3')]
```

We first split up the above expression into:

- `/article[about(./abstract, 't1/p1/p2/t3/p3')]`  
- `/section[about(./header, 't1/p1/t2/p2/p3')]`  
- `/p[about(., 't1/p1/p2/p3/p3')]

All of the patterns above produce intermediate result node-sets that have to be structurally correlated to each other. We can choose to perform a top-down correlation sequence, or a bottom-up correlation sequence consisting of containment joins. The choice between a top-down or bottom-up sequence can be an optimization decision, made at runtime by the retrieval system. For example, if a collection contains many paragraph elements, not contained within article elements, the system might decide to limit the amount of unnecessary executed *about* predicates by choosing a top-down approach. In the current implementation, the patterns are always processed top-down.

5. EXPERIMENTS

For the content only (CO) topics, we designed three experimentation runs. The first run (\(R_{art}\)) represents the baseline run of ‘flat-document’ retrieval, i.e., retrieval of documents which possess no structure. After examination of the document collection, we decided to perform retrieval of article-components. The second run regarded all subtrees in the collection as separate documents (\(R_{comp}\)). For the third run we re-used the result sets of the second run and used a log-normal distribution to model the quantity dimension (\(R_{comp-logn}\)). To penalize the retrieval of extremely long document components, as well as extremely short document components, we set the mean at 2516. Experiments for INEX 2002 showed that 2516 words was the average document component length of relevant document components according to the strict evaluation function used in INEX 2002. Table 7 gives a summary of our experimentation runs.

Table 7: Original CO experimentation runs; note that we used a length of 2516 as preferred component length for the \(R_{comp-logn}\) run. The experiments for INEX 2002 showed 2516 was the average document component length of relevant components, according to the strict evaluation function used in INEX 2002.

<table>
<thead>

</tr>
<tr>
<td>(R_{comp-logn})</td>
<td>{tr(‘*’)}</td>
<td>top., quant.(2516)</td>
<td>0.0374</td>
</tr>
</tbody>
</table>

The originally submitted CO-runs all used the keywords present in the keyword-element of each topic. Before executing each topic, query stop words were removed using the SMART query stop word list, and all remaining keywords were stemmed with the Porter stemmer. Stop word removal (using the SMART stop word list) and stemming was also performed on the indexed collection terms, as well as the removal of those terms shorter than 2 characters and longer than 25 characters.

We performed several additional CO runs of which the mean average precision values are summarized in Table 8.\(^2\) First, we extracted, for each topic, the terms occurring in the title *about* clauses (\(T\)) and in the description (\(D\)) and keyword (\(K\)) component text. We then made combinations of the \(T\), \(D\) and \(K\) keyword sets, and used the combinations in additional runs (\(TD\) and \(TK\)). Second, we also created CO-runs where we replaced the log-normal element length prior (logn runs) with a standard element length prior (logs runs):

\[
lp(E) = \log(P(E)) = \log(\sum t f(t, E))
\]

Finally, after observing a big difference in system performance with the approach by Sigurbjörnsson, Kampis and de Rijke [19], which is based on the same language modeling technique, we decided to reproduce their approach of combining surrounding document evidence with element evidence (*awr runs*).

From the average precision values in Table 8, the following observations are clear:

- large elements should not be discounted (under the current metrics of evaluation; difference between logn and logs runs);
- combining element scores with their surrounding con-

\(^2\)The differences between the \(R_{comp}\) and \(R_{comp-logn}\) MAP scores in Tables 7 and 8 originate from the (different) ordering of elements with equal score.
We plan to further investigate the cause of the performance difference between the \textit{logn} and \textit{logs} runs. One explanation could be that the log-normal’s mean value of 2516 words, as desired component size, is not the correct value given the relevance assessments. Another explanation for this discrepancy between evaluation results and our intuition, expressed in the log-normal length prior, could be sought in the current evaluation metrics that reward exhaustivity over specificity.

Besides measuring the effectiveness of our retrieval system, we also measured the efficiency of indexing and querying the collection. Table 9 shows the average topic execution times of all created runs. For a given run, we averaged the topic execution times of the topics in that given run (with CO runs having 36 topics and the SCAS and VCAS runs having 30 topics). All measurements are wallclock timings, measured in seconds. The hardware used for the executions of the runs is an AMD Opteron machine, running at 1.4GHz and having 2GB of main memory. The indexing time is divided into two separate parts:

- the time needed for insertion of data $T_{\text{insert}}$, measured at 176 seconds;
- the time needed for post-processing $T_{\text{postprocess}}$, measured at 191 seconds. Post-processing consists of determining collection frequencies, component text lengths (component lengths disregarding markup) and indexing of topics.

Memory use of our system varied between 250MB and 1GB, where 1GB was reached when materializing large components, or large component sets (large with regard to the number of components in the result set) for executing the language model. Moreover, memory use was increased by behavior of the database kernel used: the kernel loads tables completely into memory when they are needed, even if not all parts of the table are used. This redundant memory use as a result of loading irrelevant data can be avoided by, for example, horizontal fragmentation of the tables as in [18]. The extra time needed for the \textit{logn} and \textit{logs} runs (when compared to the \textit{comp} run) can be explained by extra join-operations against parts of the index, needed for retrieving the component text lengths and calculation of the logarithm values. Also, the \textit{aw} runs take more execution time as a result of the extra containment joins needed to resolve the specified structural constraints.

The time needed for indexing can be reduced further. First, for the sake of simplicity, the system indexes the full XPath (in string format) for each component in the collection. This full XPath indexing is redundant and can be replaced by a facility to resolve the component XPaths when presenting results to the user, or by a more compact index structure. Second, we are looking into possibilities for encoding other parts of the index into more compact structures, e.g., bitvectors.

6. CONCLUSIONS AND FUTURE WORK

Our participation in INEX can be summed up as an exercise in applying current and state of the art information retrieval technology to a structured document collection. We described a relatively straightforward approach to simplify the implementation of retrieval models that combine structural and content properties. We hope to take advantage of this flexibility to a larger extent in our future research, as the current approach to retrieval has only used a small proportion of all the structural information present in XML documents. Other research includes more extensive experimentation in the area of relevance feedback, and develop a different normalization mechanism to remove the bias of the language model on short components. Lastly, we aim to improve the efficiency of the system, both memory and CPU wise, by applying horizontal fragmentation and encoding of data into more compact structures.
