# The Ring Loading Problem* 

Alexander Schrijver ${ }^{\dagger}$<br>Paul Seymour ${ }^{\ddagger}$ Peter Winkler ${ }^{\S}$

#### Abstract

The following problem arose in the planning of optical communications networks which use bidirectional SONET rings. Traffic demands $d_{i, j}$ are given for each pair of nodes in an $n$-node ring; each demand must be routed one of the two possible ways around the ring. The object is to minimize the maximum load on the cycle, where the load of an edge is the sum of the demands routed through that edge.

We provide a fast, simple algorithm which achieves a load that is guaranteed to exceed the optimum by at most $3 / 2$ times the maximum demand, and that performs even better in practice. En route we prove the following curious lemma: for any $x_{1}, \ldots, x_{n} \in[0,1]$ there exist $y_{1}, \ldots, y_{n}$ such that for each $k,\left|y_{k}\right|=x_{k}$ and $$
\left|\sum_{i=1}^{k} y_{i}-\sum_{i=k+1}^{n} y_{i}\right| \leq 2 .
$$ [This article is reprinted here (with updates) from SIAM J. Discrete Math., 11 (1998), pp. 1-14. New developments include a $1+\varepsilon$ approximation algorithm and a variation of ring loading in the setting of wavelength division multiplexing; remarks added for this printing, about these and other issues, are enclosed in brackets.]

I. Introduction. Around the world, billions of dollars are being spent by telephone operating companies to replace copper circuits with optical fiber, vastly increasing potential bandwidth and opening the network to multiple data types, including video. The dominant technological standard in the United States is the Synchronous Optical NETwork (SONET) [1]. In one very popular configuration, called a SONET ring, nodes (typically telephone central offices) are connected by a ring of fiber, with each node sending, receiving, and relaying messages by means of a device called an add-drop multiplexer (ADM).

SONET rings enjoy several advantages over other network configurations. The vertex-symmetry of the rings ensures that nodes play the same role and are similarly equipped, and the connectivity of the cycle protects against failure of either a

[^0]link (that is, an edge) or a node. Thus, a major task of network-planning software, including Bellcore's SONET Toolkit [3], is to identify groups of nodes that can be turned into SONET rings in such a way as to satisfy traffic demands in a cost-efficient manner.
[As of the middle of 1999, SONET rings are carrying a large part of this nation's long-distance telephone traffic, and with it, of course, a great deal of internet traffic. Many of the rings have capacity "OC-48," meaning that they can carry 2.5 billion bits per second. New rings of size OC-192 are already contemplated. In Europe, a standard similar to SONET, called SDH (Synchronous Digital Hierarchy), is in effect.]

The capacity of a SONET ring varies from ring to ring but is the same for each link of a ring, and the cost of a ring (all other factors being equal) is an increasing function of its capacity. It is not the fiber itself but the ADMs that limit bandwidth. However, the effect is the same: for each SONET ring there is a capacity $C$ such that no link of the ring may carry more than $C$ units of traffic.

In some SONET rings all traffic is routed clockwise (unless a fault has occurred) and the capacity is selected so as to handle the sum of all the point-to-point demands between nodes of the ring. Such "unidirectional" SONET rings will not concern us here.

In bidirectional rings, however, a routing is chosen independently for each pair of nodes, and all traffic between those nodes (in either direction) is sent by that route. Clearly, bidirectional rings are much more bandwidth efficient; for example, when demands are uniform they can carry four times the traffic of a unidirectional ring having the same capacity.

In order to compute the capacity required for a proposed bidirectional SONET ring, the planning software must route the projected traffic demands in such a way as to minimize, or at least approximately minimize, the maximum load on any link. The problem is described formally below. We remark that the actual capacity selected for a proposed ring is further adjusted to allow for failures and abnormal demands, and that there is a discrete set of standard capacities from which to choose; but these considerations do not change the objective.
[Problems similar to the one considered in this paper have arisen in a new technology called wavelength division multiplexing (WDM). Here many signals are sent simultaneously through the same fiber at different wavelengths. Because it is difficult to change the wavelength of a given signal without an optical-to-electronic-to-optical conversion, wavelength assignment problems arise as well as routing problems. Later we will indicate how the method used here for the SONET ring loading problem was adapted to WDM rings.]
2. Notation and Terminology. The problem is formally stated as follows: RING LOADING Instance: Ring size $n$ and nonnegative integers $d_{i, j}, 1 \leq i<j \leq n$.
QUestion: Find a map $\phi:\{(i, j): 1 \leq i<j \leq n\} \longrightarrow\{0,1\}$ which minimizes $L=\max _{1 \leq k \leq n} L_{k}$, where

$$
L_{k}=\sum\left\{d_{i, j}: \phi(i, j)=1 \text { and } k \in[i, j)\right\}+\sum\left\{d_{i, j}: \phi(i, j)=0 \text { and } k \notin[i, j)\right\} .
$$

The notation " $i, j$ )" is used here for the half-closed integer interval $\{i, i+1, \ldots$, $j-1\}$.

To make Ring loading a decision problem as in [8], we append a target value $T$ to the instance and ask whether there is a $\phi$ for which $L \leq T$.

Each $d_{i, j}$ is called a demand, and the map $\phi$ is called a routing. Setting $\phi(i, j)=0$ amounts to routing the traffic between nodes $i$ and $j$ the "back" way, that is, through the link $\{n, 1\}$. When $\phi(i, j)=1$ we say that the $(i, j)$ th demand has been routed through the "front."

The routing induces a load $L_{i}$ on each link $\{i, i+1\}$, namely, the sum of the demands routed through that link. The largest load is the ringload $L$, the quantity to be minimized.
3. Theory and Reality. The decision form of Ring loading is clearly in the class NP since the routing provides a witness that is only $\binom{n}{2}$ bits long. In fact, RING LOADING is an integer multicommodity flow problem (the reader is referred to [5] for a survey of such problems); in general, such problems are NP-complete, but we are dealing with a very special case.

Technically, the input size for an instance of RING LOADING is slightly more than

$$
\lceil\log n\rceil+\lceil\log T\rceil+\sum_{1 \leq i<j \leq n}\left\lceil\log d_{i, j}\right\rceil
$$

relative to which RING LOADING is NP-complete. A simple reduction is available from the PARTITION problem [8, p. 223], in which positive integers $a_{1}, \ldots, a_{m}$ are given and the question is whether one can divide them into two groups of equal sum. Put $n=m+3, d_{i, m+2}=a_{i}$ for $1 \leq i \leq m$, and $d_{m+1, m+2}=d_{m+2, m+3}=\sum a_{i} / 2$. Set all other demands equal to zero, and let $T=\sum a_{i}$. Then a good routing must send $d_{m+1, m+2}$ and $d_{m+2, m+3}$ the short way (front) and must partition the other demands so that $L_{m+1}=L_{m+2}=T$. This solves Partition, and vice versa.

An even easier reduction-with just two nodes-was given by Cosares and Saniee [4] and was made possible by their slightly more general RING LOADING formalization in which more than one demand per node pair is allowed. (The positive results to follow are also easily extended to cover the more general formulation; we prefer the more restrictive version for notational reasons.)

However, the reduction from Partition says nothing about the tractability of RING LOADING in practice, because PARTITION is solvable in time polynomial in $m$. $\max a_{i}$ and actual demand sizes for Ring Loading are not large numbers. In fact, traffic demands are estimates to begin with, and the range 0 to 100 units is typically adequate. Thus, we may even take the maximum demand $D$ to be bounded by a reasonable constant. The size $n$ of a SONET ring is currently restricted to about 20. With these parameters, an instance of partition can be solved using dynamic programming by hand!

Modest as the parameters are, however, they do not permit exhaustive search of the $2^{\binom{n}{2}}$ possible routings, and the PARTITION-to-RING-LOADING reduction does not appear to permit reversal. As far as we know, any of the following three statements may be true (see [8] for descriptions of CLIQUE and CHROMATIC NUMBER):

- Ring loading (like partition) can be solved in time polynomial in $n$ and D.
- Ring loading (like clique) can be solved in time polynomial in $n$ but only if a bound on the maximum demand $D$ is fixed.
- Ring loading (like chromatic number) is NP-complete even for (some) fixed $D$.
Mercifully, the $D=1$ case is solvable in time polynomial in $n$. The proof is due to Frank [6] and is explained nicely in [7]; it relies on a theorem of Okamura and Seymour [12]. This case is important because in some cases demands can be split, but only at
integral values, and can thus be regarded as a multiplicity of unit demands. In fact, as we shall demonstrate, our approximation algorithm for RING LOAIING; act ually solves this case exactly.

We do not have a fast exact algorithm, either in theory or in practice, for the RING loading problem with $D>1$. Fortunately, in practice, a reasonable approximate solution to RING LOADING was acceptable. There was no room for compromise on the issue of computation time: the RING LOADING problem had to be solved in a matter of seconds at most, because it was part of a frequently called subrout ine for determining the cost of proposed SONET rings. The full program considers enormons numbers of potential SONET rings and is supposed to work on run-of-the-mill serial computers.

To be precise, we sought an algorithm $A$ with the following three properties, listed in order of importance:

1. A must be fast.
2. A should provide a solution to Ring loading; that exeede the opt imum load by no more than about $5 \%$ in most cases.
3. A should, if possible, come with a performance guaranter for both properties 1 and 2.
As it turns out, these properties were obtainable with a fairly simple algorithm whose efficiency does not much depend on $D$ (the demands can be treated as real mumbers).
4. Linear Relaxation. The "relaxed" version of Rive; iosamive, in which demands may be split (that is, sent partly around the from. partly aromul the back), is formulated as follows:

RELAXED RING LOADING
INSTANCE: Ring size $n$ and nomegative integers $d_{1, j} .1 \leq i<j<n$.
QUESTION: Find a map $\phi^{*}:\{(i, j): 1 \leq i<j<n\} \cdots(0,1)$ whin minimizes $L^{*}=\max _{1 \leq k \leq n} L_{k}^{*}$, where

$$
\left.L_{k}^{*}=\sum\left\{\phi^{*}(i, j) d_{i, j}: k \in[i, j)\right\}+\sum\left\{\left(1 \cdots \sigma^{*}(i, j)\right) d_{i, j}: k ; \mid i, j\right)\right\} .
$$

Since this is now a linear programming problem, it is solvable in prlymmial time [9]. In fact, we shall see that a solution to RELAXED MIN: 1, ©Abus; (can be ohtained in a very fast greedy fashion, even if we demand the additional property duseribed in Proposition 4.1.

It is useful to think of demands geometrically an wodged chords in a rirche representing the SONET ring. Two demands $d_{y, h}$ and $d_{1, j}$ winh! $h$ and $i<j$, are said to cross if all of the indices are distinct and if examtly one of a and o lies in (g, h): otherwise they are said to be parallel. In particular. demands such an $d_{2}$, and $d_{1, k}$. which share a node, are parallel.

A link which lies between two chords representing parallel domands is said to
 problem is said to split a demand $d_{2, j}$ if $0<\sigma^{*}(i, j)-1$.
 which achieves the optimal load $L^{*}$ and is also minimal, on the sernse that no other routing has $L_{i} \leq L_{i}^{*}$ for every $i$ and $L_{j}<L$; for some 1 . Thern wo lunk whert lies between two parallel demands will carry traffic from both de manuds.

Proof. Assume otherwise, letting link $\{k, k+1\}$ carry a quantity a of traffic from demand $d_{g, h}$ and $b \geq a$ from $d_{i, j}$. After reronting a quantity a of waflie from cach demand so as to no longer pass through the $k$ th link, no link muffers wh incromed load. This contradicts the minimality of $\phi^{*}$.

Proposition 4.1 fails for Ring Loading, as can be seen from the example in Figure 4.1, where $n=8$ and the nonzero demands are $d_{2,3}=d_{1,4}=1$ and $d_{6,7}=$ $d_{5,8}=2$. The optimal \{0,1\}-assignment sends both $d_{1,4}$ and $d_{5,8}$ the long way around the ring, achieving $L=3$; no other assignment can do better than $L=4$. What is significant, however, is that the proposition does hold in the case of $\{0,1\}$ demands.

We can turn relaxed ring loading into a decision problem in a more general way than before. We append to the instance a capacity $C_{i}$ for each link $\{i, i+1\}$ and ask whether there is a routing $\phi^{*}$ for which $L_{i} \leq C_{i}$ for each $i$. In the following it will be useful to regard node labels as integers modulo $n$, so that, for example, the link $\{n, 1\}$ is also written $\{n, n+1\}$ and the half-open interval ( $g, h$ ] is interpreted as $\{g, g+1, \ldots, n-1, n, 1,2, \ldots, h-1\}$ if $h<g$.

Each pair of links $\{g, g+1\},\{h, h+1\}$, with $g<h$, constitutes a cut of capacity $C_{g}+C_{h}$ in the network. We may think of a cut as a chord connecting the midpoints of the links $\{g, g+1\}$ and $\{h, h+1\}$; if a demand $d_{i, j}$ crosses this chord, any routing will contribute load $d_{i, j}$ to the cut's two links. Thus, if the instance is solvable, then $D_{g, h} \leq C_{g}+C_{h}$, where

$$
D_{g, h}:=\sum\left\{d_{i, j}: i \leq g \text { and } j \in(g, h], \text { or } i \in(g, h] \text { and } j>h\right\}
$$

is the total traffic demand across the cut. The following converse is a special case of the Okamura-Seymour theorem [12]; we give a simple proof here.

Proposition 4.2. If $D_{g, h} \leq C_{g}+C_{h}$ holds for each cut, then there is a solution to RELAXED RING LOADING satisfying the capacity constraints.

Proof. It will be useful in what follows to allow "cuts" of the form $\{g, g\}$, with capacity $2 C_{g}$ and demand $D_{g, g}=0$. The cut constraint for these cuts is thus equivalent to nonnegativity of the link capacities.

Assume the theorem fails and fix a counterexample with $n$ minimal and, subject to the minimality of $n$, having the least possible number of nonzero demands.

Choose any nonzero demand-say, $d_{i, j}$-with $i<j$, and let $\{g, h\}$ minimize $M=D_{g, h}-C_{g}-C_{h}$ subject to $i \leq g<h<j$; thus, $\{g, h\}$ is the tightest cut in the front route for $d_{i, j}$. (A cut $\{g, h\}$ is said to be "tight" if $D_{g, h}=C_{g}+C_{h}$.)

We propose to send $\min \left(d_{i, j}, M / 2\right)$ of the demand $d_{i, j}$ around the front and, if $d_{i, j}>M / 2$, send the remaining $d_{i, j}-M / 2$ around the back. When the capacities have been decreased accordingly, we will have a new RELAXED RING LOADING instance with one less nonzero demand. If the new instance still satisfies the cut constraints, it will contradict minimality of the counterexample, proving the theorem.

Suppose that in the new instance some cut is violated. That cut must lie on the back route for $d_{i, j}$, since this demand has already been accounted for in cuts which it crosses, and cuts on the front route have sufficient slack by choice of $M$. Then we have a cut $\left\{g^{\prime}, h^{\prime}\right\}$ with $\left[g^{\prime}, h^{\prime}\right) \cap[i, j)=\emptyset$ such that

$$
D_{g^{\prime}, h^{\prime}}+2\left(d_{i, j}-M / 2\right)>C_{g^{\prime}}+C_{h^{\prime}}
$$

where all quantities are computed in the original instance.
Call the $\{g, h\}$ cut and the $\left\{g^{\prime}, h^{\prime}\right\}$ cut "straight" and consider also the "diagonal" cuts $\left\{g, g^{\prime}\right\}$ and $\left\{h, h^{\prime}\right\}$. Every demand must cross at least as many of the two diagonal cuts as the two straight cuts, while $d_{i, j}$ crosses both diagonal cuts and neither straight

Fig. 4.I An instance of RING LOADING with optimal solution.
cut. Hence,

$$
\begin{aligned}
D_{g, g^{\prime}}+D_{h, h^{\prime}} & \geq D_{g, h}+D_{g^{\prime}, h^{\prime}}+2 d_{i, j} \\
& >C_{g}+C_{h}-2(M / 2)+C_{g^{\prime}}+C_{h^{\prime}}-2\left(d_{i, j}-M / 2\right)+2 d_{i, j} \\
& =C_{g}+C_{g^{\prime}}+C_{h}+C_{h^{\prime}}
\end{aligned}
$$

so that one of the diagonal cuts must have violated the cut constraint.

Note that nonviolation of cuts of the form $\{g, g\}$ assures us that the given routing of $d_{i, j}$ is actually possible, i.e., that no link capacity will become negative afterward.

Given a set of demands, we now wish to find an assignment $\phi^{*}$ which minimizes $L^{*}$ and satisfies the conclusion of Proposition 4.1. This can be done quickly by putting each link in a tight cut as follows.

First we compute the $\binom{n}{2}$ values $D_{g, h}, 1 \leq g<h \leq n$; let the largest of these be $M$. Then $L^{*} \geq M / 2$, but the ring with all capacities set to $M / 2$ satisfies the cut constraint, so in fact $L^{*}=M / 2$. We now take the links in any order (say, $\{1,2\}$ through $\{n, 1\}$ ) and lower their capacities as much as possible; that is, define capacities $\left\{C_{i}\right\}$ recursively by

$$
C_{g}=\max \left(\max h<g\left(D_{g, h}-C_{h}\right), \max h>g\left(D_{g, h}-M / 2\right)\right),
$$

noting that $C_{g} \geq 0$.
No realizable set $\left\{C_{i}^{\prime}\right\}$ of capacities can have $C_{i}^{\prime} \leq C_{i}$ for every $i$ and $C_{j}^{\prime}<C_{j}$ for some $j$, since the least such $j$ would be part of a bad cut. Hence any feasible assignment $\phi^{*}$ for these capacities is a minimal solution of the original RELaxed ring loading instance, and Proposition 4.1 applies. In particular, if $S=$ $\left\{\{i, j\}: d_{i, j}\right.$ is split by $\left.\phi^{*}\right\}$, then every pair of chords in $S$ crosses and, therefore, $|S| \leq n / 2$.

In fact, after reducing the capacities as above we can solve RELAXED RING LOADING to route each demand all front or all back until only mutually pairwise crossing demands remain. To see this, assume that there is still a parallel pair of unrouted demands and choose a link between them; fix a tight cut containing that link. At most one of the two parallel demands crosses the cut; the other can, and indeed must, be routed to miss the cut entirely.

In summary, our algorithm for solving relaxed Ring loading proceeds as follows:

1. Compute the $\binom{n}{2}$ values $D_{g, h}$, and $L^{*}=M / 2$.
2. Compute minimal capacities $\left\{C_{i}\right\}$ as described above.
3. While there are pairs of parallel demands, find tightest cuts and route demands all front or all back, resetting capacities accordingly.
4. When only crossing cuts remain, route as much as possible by the front and the remainder by the back.
The running time of this procedure is approximately of order $k n^{2}$, where $k$ is the number of nonzero demands; this is very fast for the parameter sizes that we require. See [13] for an even faster solution to problems akin to RELAXED RING LoAding.
[In [11] a clever combinatorial method for solving Relaxed Ring loading is presented, which runs in time only $O(n k)$. It is used there to obtain only a factor-of- 2 approximation to RING LOADING, but we will see later that the methods here (with any means of solving relaxed ring loading) can be adapted to approximate the optimal solution within a factor of $1+\varepsilon$ for any $\varepsilon>0$.]

In any case, our solution to RELAXED RING LOADING ends with at most only $n / 2$ of the demands split. It therefore seems natural to compute $\phi^{*}$ and then "unsplit" the demands in $S$ as gently as possible in order to get a near-optimal $\{0,1\}$ assignment for Ring loading. This is exactly what we do.
5. Unsplitting. Henceforth $\phi^{*}$ will be a fixed, minimal solution to RELAXED RING Loading with a set of split demands $S$ as above. We seek a solution $\phi$ to RING LOADING which agrees with $\phi^{*}$ when $\phi^{*}(i, j) \in\{0,1\}$ and for which $L-L^{*}$ is as small as possible, where $L$ is the ringload of $\phi$.

If node $i$ is not an endpoint of a split demand, then the difference between the loads on links $\{i-1, i\}$ and $\{i, i+1\}$ will not change as we pass from $\phi^{*}$ to $\phi$. Hence, for the purpose of determining $\phi$, we may as well delete vertex $i$ and combine the two former links to form a single link whose load under the relaxed assignment is taken to be $\max \left(L_{i-1}^{*}, L_{i}^{*}\right)$. Proceeding in this fashion for each vertex not involved in a split demand, we are reduced to the case where $n$ is even and $S=\{\{i, i+m\}: 1 \leq i \leq m\}$, with $m=n / 2$.

Let us define $u_{i}$ to be the amount of demand $d_{i, i+m}$ sent by $\phi^{*}$ via the front route, and $v_{i}$ via the back, so that $u_{i}, v_{i}>0$ and $u_{i}+v_{i}=d_{i, i+m}$. If $\phi$ routes $d_{i, i+m}$ by the front, then each link $\{j, j+1\}$ with $j \in[i, i+m)$ has its load incremented by $v_{i}$ (the amount formerly sent around the back) relative to the relaxed assignment $\phi^{*}$, while the rest of the link loads are decremented by $v_{i}$. Similarly, if demand $d_{i, i+m}$ is sent by the back route, the load of each link in $[i, i+m]$ is decreased by $u_{i}$ while the rest are incremented by the same amount.

Hence if we set $z_{i}=v_{i}$ when $\phi(i, i+m)=1$, and $z_{i}=-u_{i}$ otherwise, we have

$$
L_{j}=L_{j}^{*}+\sum_{\substack{i \in[1, m] \\ j \in[i, i+m)}} z_{i}-\sum_{\substack{i \in[1,, m] \\ j \in[i+m, i)}} z_{i} .
$$

Notice that $L_{j}+L_{j+m}=L_{j}^{*}+L_{j+m}^{*}$ for all $j$. Thus $L \leq 2 L^{*}$ for all choices of $\phi$, duplicating the performance ratio claimed by Cosares and Saniee [4], but we will do much better by choosing $\phi$ judiciously.

The optimal $\phi$ can be found by dynamic programming, but in practice we try every $\phi$ and choose the best one! There are at most $2^{n / 2}$ choices for $\phi$, a list easily exhausted for all currently contemplated SONET ring sizes. In effect, for our values of $n$ (up to 32 , possibly) the line between tractability and intractability lies not between polynomial and exponential but between exponential in $n$ and exponential in $n^{2}$.

Our embarrassment, as theorists, is assuaged somewhat by the fact that there is a polynomial algorithm for finding an assignment $\phi$ that achieves the performance guaranteed by the following theorem.

Theorem 5.1. Let $\phi^{*}$ be a minimal solution, with ringload $L^{*}$, to the relaxed version of an instance of RING Loading. Let $D$ be the maximum magnitude of the demands split by $\phi^{*}$. Then there is a $\{0,1\}$ assignment $\phi$ with ringload $L$ that agrees with $\phi^{*}$, except on split demands, and that satisfies $L-L^{*} \leq \frac{3}{2} D$.

Proof. We define $z_{i}$ (hence $\phi$ ) inductively, ensuring that $\sum_{i=1}^{k} z_{i} \in[-D / 2, D / 2]$ for all $k, 1 \leq k \leq m$. This is always possible since, once $z_{1}, \ldots, z_{k-1}$ are defined and the partial sum $s=\sum_{i=1}^{k-1} z_{i}$ lies in the required interval, the two possible values of $\sum_{i=1}^{k} z_{i}$ lie on both sides of $s$ and differ by only $u_{k}+v_{k} \leq D$.

Put

$$
M_{k}:=\sum_{i=1}^{k} z_{i}-\sum_{i=k+1}^{m} z_{i}=2 \sum_{i=1}^{k} z_{i}-\sum_{i=1}^{m} z_{i} \in\left[-\frac{3}{2} D, \frac{3}{2} D\right]
$$

and

$$
M:=\max _{1 \leq k \leq m}\left|M_{k}\right|
$$

then

$$
L-L^{*} \leq \max _{j}\left(L_{j}-L_{j}^{*}\right)=M \leq \frac{3}{2} D .
$$

The greedy unsplitting given in the proof of Theorem 5.1, when appended to our solution to RELAXED RING LOADING, gives the polynomial-time approximation algorithm, which we call Algorithm A.

Of course, the true optimum $L^{\text {opt }}$ for the original RING LOADING problem is at least equal to $L^{*}$, so the theorem guarantees an additive error of at most a constant $(3 / 2)$ times the maximum original demand irrespective of the value of $n$.

How good is this performance guarantee? This method can never achieve a multiplicative performance bound better than 2 relative to $L^{*}$, since the "square example" with $n=4, d_{1,3}=d_{2,4}=1$, and other demands 0 gives $L^{*}=1, L^{\mathrm{opt}}=2$. Nor can we hope to get a factor better than $4 / 3$ relative to $L^{\text {opt }}$ due to the example shown in Fig. 4.1.

However, for larger $n$, if demands average $D / 2$ in size then the typical demand adds $n / 4 \cdot D / 2$ to the total load when routed the short way; thus we expect the sum of the loads of all the links to be approximately $\binom{n}{2} \cdot n / 4 \cdot D / 2 \approx(D / 16) n^{3}$, giving $L^{*} \geq(D / 16) n^{2}$. Next to an optimum of order $n^{2}$, an additive error that does not depend on $n$ at all looks pretty good; but we must again remember that $n$ is never very large. For $n=16$ this analysis allows a relative error of $\left(\frac{3}{2} D\right) /(16 D) \approx 9 \%$, which is not so impressive. Of course this is pessimistic; the Cosares-Saniee algorithm allows $100 \%$ error in theory but does far better in practice. In any case, it would clearly be worth some effort to determine whether the constant $3 / 2$ is the best possible, and we tackle this problem in the last section.
[Thanks to Sanjeev Khanna [10], we now know that in fact our method can be used to obtain a polynomial-time approximation scheme for RING LOADING; that is, a multiplicative performance guarantee of $1+\varepsilon$ for any $\varepsilon>0$. This is achieved by first reducing the given instance to one in which the maximum demand is at most $2 \varepsilon L^{\text {opt }}$; then our additive guarantee gives the desired result. To effect the reduction, Khanna observes that no more than $3 / \varepsilon$ of the "big" demands - those which exceed $2 \varepsilon L^{\text {opt }} / 3$ in size-can be routed more than halfway around the ring, in any optimal solution. A linear program can test those small sets of big demands; this can be done in a neat combinatorial way, and without knowing the value of $L^{\text {opt }}$ in advance.]

We return now, briefly, to the $\{0,1\}$ demands case.
6. $\{\mathbf{0}, \mathbf{1}\}$ Demands. In this section it will not complicate notation to allow many demands between two nodes of the ring, each of magnitude 1; we also allow capacities $C_{i}$ for the links, not necessarily equal. A cut $\{g, h\}$ is said to be even if $C_{g}+C_{h}-D_{g, h} \equiv$ $0(\bmod 2)$. In $[7]$ feasibility is shown to be equivalent to the cut condition together with the following parity condition.

Parity condition. For every pair of links $g, h$, if $g$ and $h$ are each in a tight cut, then the cut $\{g, h\}$ is even.

Theorem 6.1. In the $\{0,1\}$ case, if we put $C_{i}=L$ for each link $i$, then RING LOADING is feasible with ringload $\leq L$ if and only if the cut and parity constraints are satisfied. If only the cut constraint is satisfied, then the optimal ringload is $L+1$. In any case, the algorithm $A$ described above finds an optimal assignment.

Proof. It is straightforward to verify that if a demand is assigned (all front or all back) without violating the cut condition, then the truth value of the parity condition is preserved. Since the parity condition is met when all demands are assigned, necessity is clear.

On the other hand, suppose that demands are assigned in accordance with Algorithm A until all remaining demands require splitting. Suppose there is at least one left, say, $d_{i, j}$; then there must be parallel cuts $\{g, h\}$ and $\left\{g^{\prime}, h^{\prime}\right\}$ on each side of $d_{i, j}$
with $C_{g}+C_{h}-D_{g, h}=C_{g^{\prime}}+C_{h^{\prime}}-D_{g^{\prime}, h^{\prime}}=1$. Since the diagonal cuts must be tight, the parity condition is (twice) violated.

It remains only to observe that if the cut constraint is satisfied when $C_{i}=L$, then at $C_{i}=L+1$ we also satisfy the parity constraint since all the cuts have slack.
[It turns out that a variation of the case of $\{0,1\}$ demands is particularly relevant for the WDM rings mentioned earlier. Here each demand is for a single-wavelength connection between two nodes of the ring; if there is more traffic than can be carried by one wavelength (unlikely), the resulting traffic requirement is rendered as separate demands for the same pair of nodes.

However, in a WDM ring, traffic demands in different directions can be handled separately, so that a general set of demands consists of ordered pairs of nodes. Each consecutive pair of nodes is connected by two links, one clockwise and one counterclockwise; the object now is to minimize the maximum traffic in any of the $2 n$ links.

In [14] several linear programs and a rounding algorithm are used to obtain an optimal routing for the WDM ring. Although the general plan is much like that used on RING loading, and fits the well-known paradigm of relaxation followed by integerization, it is unusual in achieving exact optimality.

The solution so obtained can be used directly for an optimal assignment of wavelengths, provided that there is a node at which wavelengths can be translated; otherwise the assigmment problem is NP-complete and a penalty of up to a factor of 2 in the required number of wavelengths may be incurred.

In [2], the wavelength assignment problem appears, in effect, in a purely SONET setting. The authors consider only routes that occupy the same "slot" in each link of a SONET ring, and present heuristics for solving that, again, achieve the factor-of-2 guarantee.]
7. The Constant. Let $\beta$ be the infimum of all reals $\alpha$ such that the following combinatorial statement holds: for all positive integers $m$ and nonnegative reals $u_{1}, \ldots, u_{m}$ and $v_{1}, \ldots, v_{m}$ with $u_{i}+v_{i} \leq 1$, there exist $z_{1}, \ldots, z_{m}$ such that for every $k, z_{k} \in\left\{v_{k},-u_{k}\right\}$ and

$$
\left|\sum_{i=1}^{k} z_{i}-\sum_{i=k+1}^{m} z_{i}\right| \leq \alpha
$$

Then $\beta$ is the "right" constant for Theorem 5.1; i.e., $L-L^{*} \leq \beta D$ for some choice of $\phi$. Note that any choice of rational values for the $u_{i}$ 's and $v_{i}$ 's can actually occur (up to constant factor) from an instance of RING LOADING, since we can construct one as follows. Let $M_{j}$ be the load actually incurred by link $\{j, j+1\}$ when the demands $d_{i, i+m}=u_{i}+v_{i}$ are split $u_{i}$ front and $v_{i}$ back. Let $M$ be huge, and postulate additional "short" demands $d_{j, j+1}=M-M_{j}$ for each $j, 1 \leq j \leq 2 m$. Then any optimal relaxed ring loading solution will send all the short demands by the onelink route; however, the sum of the link loads due to the other demands is constant since each has two routes of the same length. Thus splitting the other demands as given, so as to obtain the same load $M$ on every link, is optimal, and it is easy to see that no other splitting can achieve uniform load.

We already know that $\beta \leq 3 / 2$ and the square example, where $m=2$ and $u_{1}=v_{1}=u_{2}=v_{2}=1 / 2$, shows that $\beta \geq 1$. (In fact, $u_{i}$ 's and $v_{i}$ 's chosen uniformly at random subject to the given constraints also force $\beta \geq 1$.)

The special case where $u_{i}=v_{i}$ for each $i$ is interesting for several reasons. This means that $\phi^{*}$ is sending exactly half of each demand $d_{i, i+m}$ each way around the ring, giving us no clue to how to unsplit them. Furthermore, this is the case which arises when (as in the square example) all of the nonzero demands in the original RING LOADING instance are mutually crossing.

The case $u_{i}=v_{i}$ thus gives rise to a new ring loading problem as well as the following new constant.

CROSSED RING LOADING
Instance: Ring size $2 m$ and nonnegative reals $d_{i}, 1 \leq i \leq m$.
Question: Find a map $\phi:\{1,2, \ldots, m\} \longrightarrow\{0,1\}$ which minimizes $L=\max _{1 \leq k \leq 2 m} L_{k}$, where

$$
L_{k}=\sum\left\{\phi(i) d_{i}: k \in[i, i+m)\right\}+\sum\left\{(1-\phi(i)) d_{i}: k \notin[i, i+m)\right\} .
$$

Note that we have allowed real demands here (rationals would be fine, too) in order to handle nonintegral splits produced by a previous linear programming phase.

We define $\gamma$ be the infimum of all reals $\alpha$ such that the following combinatorial statement holds: for all positive integers $m$ and $x_{1}, \ldots, x_{m} \in[0,1]$ there exist $y_{1}, \ldots, y_{m}$ such that for every $k,\left|y_{k}\right|=x_{k}$ and

$$
\left|\sum_{i=1}^{k} y_{i}-\sum_{i=k+1}^{m} y_{i}\right| \leq 2 \alpha
$$

(Note that we have rescaled the combinatorial statement so that the $x_{i}$ 's lie in the unit interval instead of $[0,1 / 2]$.)

We have $1 \leq \gamma \leq \beta \leq 3 / 2$. For lack of a counterexample, the authors were moved to conjecture publicly that both constants are equal to 1 . After an embarrassingly long interval, we found a simple proof, given below, that $\gamma=1$; thus we have the following theorem.

Theorem 7.1. Let $K$ be the sum of the demands of an instance of Crossed Ring LOADING. Then there is an assignment $\phi$ (which can be found in time polynomial in $m$ and the length of the demand descriptions) whose ringload $L$ satisfies $L-K / 2 \leq D$.

Proof. We must show that given $x_{1}, \ldots, x_{m} \in[0,1]$ there are $y_{1}, \ldots, y_{m}$ such that for every $k,\left|y_{k}\right|=x_{k}$ and

$$
\left|\sum_{i=1}^{k} y_{i}-\sum_{i=k+1}^{m} y_{i}\right| \leq 2
$$

As in the asymmetric case, we can obtain a bound of 3 instead of 2 by greedy assignment; in this case that amounts to putting $y_{k}=x_{k}$ when $\sum_{i=1}^{k-1} y_{i} \leq 0$ and $y_{k}=-x_{k}$ otherwise. We generalize this algorithm by choosing a real $w$ instead of 0 as the "empty sum."

Specifically, for fixed $w \in[-1,1]$, define $y_{k}$ inductively by $y_{k}=x_{k}$ when $w+$ $\sum_{i=1}^{k-1} y_{i} \leq 0$ and $y_{k}=-x_{k}$ otherwise. Then $w+\sum_{i=1}^{k} y_{i} \in[-1,1]$ for all $k$; let $f(w):=w+\sum_{i=1}^{m} y_{i}$.

Suppose that $f(w)=-w$; then

$$
\begin{aligned}
\sum_{i=1}^{k} y_{i}-\sum_{i=k+1}^{m} y_{i} & =2 \sum_{i=1}^{k} y_{i}-\sum_{i=1}^{m} y_{i} \\
& =2\left(w+\sum_{i=1}^{k} y_{i}\right)-\left(w+\sum_{i=1}^{m} y_{i}\right)-w \\
& \in[-2,2]
\end{aligned}
$$

as desired.
Since $f(-1)+(-1) \leq 0 \leq f(1)+1$, the existence of a $w$ for which $f(w)=-w$ would follow from the intermediate value theorem if $f$ were continuous. Of course this is not the case; whenever a partial sum hits 0 , some $y_{i}$ 's change sign and $f(w)$ may jump. (Since we have chosen $y_{i}$ positive when the partial sum is $0, f$ will be continuous from the left.) However, it turns out that the absolute value of $f$ is continuous.

Note first that when no partial sum is at 0 , the derivative $f^{\prime}(w)$ is 1 . On the other hand suppose that $w=w_{0}$ is chosen such that one or more of the partial sums is zero; in particular, let $k \geq 0$ be minimal such that $w+\sum_{i=1}^{k} y_{i}=0$. Then for sufficiently small $\varepsilon$, the signs of $y_{j}$ and $w+\sum_{i=1}^{j} y_{i}$, for $j>k$, flip as we move from $w=w_{0}$ to $w=w_{0}+\varepsilon$. Hence, taking $j=m$, we have that $\lim _{w \rightarrow w_{0}^{+}} f(w)=-f\left(w_{0}\right)$.

It follows that when any partial sum hits zero we will have $\lim _{w \rightarrow w_{0}^{+}} f(w)=$ $-f\left(w_{0}\right)$; thus the function $g$ given by $g(w)=|f(w)|$ will be continuous everywhere and differentiable except at finitely many points. The graph of $g$ is a zig-zag, with derivative 1 where $g(w)=f(w)$, and -1 where $g(w)=-f(w)$.

Of course, if we define $h$ by $h(w)=-w$, then the graph of $h$ is a line of slope -1 from $(-1,1)$ to $(1,-1)$ which must intersect the graph of $g$. Moreover, it must either intersect at a point where $g^{\prime}(w)=1$ or coincide with a segment of the graph of $g$ of slope -1 , in which case the leftmost point of the segment lies also on the graph of $f$. Either way we have a point $w$ at which $-w=g(w)=f(w)$.

To complete the proof we need to demonstrate a fast algorithm for finding this $w$. To do this we set the $y_{i}$ 's one at a time while keeping a solution $w$ in range. Specifically, at stage $j$ we have values $y_{1}, \ldots, y_{j}$ fixed and $a_{j} \leq w \leq b_{j}$, with $g\left(a_{j}\right) \leq-a_{j}$ and $g\left(b_{j}\right) \geq-b_{j}$; of course this holds at stage 0 with $a_{0}=-1, b_{0}=1$. At stage $j+1$, if $a_{i}+\sum_{i=1}^{j} y_{i}$ and $b_{i}+\sum_{i=1}^{j} y_{i}$ are both positive, then perforce we set $y_{j+1}=-x_{j+1}$; if both are $\leq 0$, then we put $y_{j+1}=x_{j+1}$. In either of these cases we set $a_{j+1}=a_{j}$ and $b_{j+1}=b_{j}$.

Otherwise $s:=-\sum_{i=1}^{j} y_{i}$ lies in the half-open interval $\left[a_{j}, b_{j}\right)$. If $g(s)<-s$, we put $y_{j+1}=-x_{j+1}$ and set $a_{j+1}=s$ and $b_{j+1}=b_{j}$; if $g(s) \geq-s$, put $y_{j+1}=x_{j+1}$ and set $a_{j+1}=a_{j}$ and $b_{j+1}=s$. In any case the inductive conditions are preserved, the intervals $\left[a_{j}, b_{j}\right]$ are nested downward, and at stage $m$ all the $y_{i}$ 's are correctly set.

We have shown $\gamma=1$, but the proof above will not work for $\beta$, as $g=|f|$ is no longer continuous in the asymmetric case. Even so, we may gain by replacing $f$ by a multivalued function $F$, defined by $z \in F(w)$ if $z=w+\sum_{i=1}^{n} z_{i}$ for any $z_{1}, \ldots, z_{n}$ which keep the sums $w+\sum_{i=1}^{k} z_{i}$ within bounds.

Then the graph of $F$ will be a union of slope-1 line segments, each corresponding to an assignment of $z_{i}$ 's. The sum of the lengths of these segments will be at least $\sqrt{2}$ since $F(w)$ always takes on at least one value, and in practice - and in virtually

Fig. 7.I An example in which additive error of $D$ cannot quite be achieved.
any random model - the segments will almost always intersect the line from ( $-.5, .5$ ) to $(.5,-.5)$ at least once, providing a solution to RING LOADING which is within $D$ of $L^{*}$.

However, it is just barely possible to choose values $u_{i}$ and $v_{i}$ for which the diagonal line sneaks through between the line segments of the graph of $F$. A set of such values, for $m=13$, is given in Figure 7.1 along with the corresponding graph of $F$. On the

| 32 | 496 | $92 \%$ | .00000 | $99 \%$ | .0002 | $29.2 \%$ | .00037 | $26.4 \%$ | .02 | .019 | 1.1 |

graph, each of the $2^{13}$ routings is represented by a diagonal line segment, often null, indicating the final sum $w+\sum_{i=1}^{m} z_{i}$ as a function of $w$, for just those values of $w$ for which all partial sums $w+\sum_{i=1}^{k} z_{i}$ lie between -.5 and .5 .

With this general definition of the multifunction $F$, a crossing of the diagonal is necessary as well as sufficient to get a solution within 2 of $L^{*}$. Hence the example shows that $\beta$ is at least 1.01. This lower bound can certainly be raised somewhat but it is far from clear that the true value of $\beta$ is anywhere near $3 / 2$.
8. Conclusions. Experimental results show that indeed our proposed algorithm is adequately fast and, when applied to random examples small enough to compute $L^{\text {opt }}$, produces a ringload very close to optimal. We have never managed to produce a random example with $L>L^{*}+D$ even though our theorem guarantees only $L \leq$ $L^{*}+\frac{3}{2} D$, and we doubt such an instance will ever be seen in practice.

Hence, even though the mathematics refuses to cooperate, we guarantee $L \leq$ $L^{*}+D$.

Table 8.1 exhibits the results of testing our algorithm, which we call Algorithm A, on uniformly random data. Alongside A we ran a linear programming algorithm, Algorithm B , in order to compute the lower bound given by the Relaxed Ring LOADING solution. To find the optimum ringload and for purposes of comparison, we also tested Algorithm C, which recursively looks for an optimal solution. In most cases Algorithm C was not enormously slower than A, but it became hopelessly stuck in some cases, leaving us with no value for the optimal ringload.

For each set of parameters, 1000 cases were run. The interpretation of the columns of the table is as follows:
$n$ : number of nodes in the ring,
$k$ : number of demands,
$\mathrm{C} \%$ : percentage of runs in which the optimum was found,
$\mathrm{C}-\mathrm{B}$ : average error of LP bound relative to optimum,
$\mathrm{B}=\mathrm{C}$ : percentage of runs in which LP bound $=$ optimum,
A-C: average error of our algorithm relative to optimum,
$\mathrm{A}=\mathrm{C}$ : percentage of cases in which A hit the optimum,
$\mathrm{A}-\mathrm{B}$ : average error of LP bound relative to A ,
$\mathrm{A}=\mathrm{B}$ : percentage of cases in which A achieves LP bound,
Bt: average running time for the LP algorithm,
At: average running time for Algorithm A,
Ct: average running time for Algorithm C.
The fourth through seventh columns are computed only for those rounds in which the optimum was found; that creates a bias, especially for the column labelled $\mathrm{B}=\mathrm{C}$, since we will probably never get equality when Algorithm $C$ fails. The run time for

Algorithm C includes cases where it failed to find the optimum, and it was terminated after 10 seconds of CPU time on any one run.

Acknowledgments. The authors have had the benefit of valuable conversations with Noga Alon and Milena Mihail.
