ABSTRACT

We present the results of a four-month campaign searching for low-frequency radio transients near the North Celestial Pole with the Low-Frequency Array (LOFAR), as part of the Multifrequency Snapshot Sky Survey (MSSS). The data were recorded between 2011 December and 2012 April and comprised 2149 11-min snapshots, each covering 175 deg². We have found one convincing candidate astrophysical transient, with a duration of a few minutes and a flux density at 60 MHz of 15–25 Jy. The transient does not repeat and has no obvious optical or high-energy counterpart, as a result of which its nature is unclear. The detection of this event implies a transient rate at 60 MHz of $3.9_{-3.7}^{+14.7} \times 10^{-4} \text{ d}^{-1} \text{ deg}^{-2}$, and a transient surface

*E-mail: adam.stewart@physics.ox.ac.uk

density of $1.5 \times 10^{-5} \text{ deg}^{-2}$, at a 7.9-Jy limiting flux density and ~ 10 -min time-scale. The campaign data were also searched for transients at a range of other time-scales, from 0.5 to 297 min, which allowed us to place a range of limits on transient rates at 60 MHz as a function of observation duration.

Key words: instrumentation: interferometers – techniques: image processing – radio continuum: general.

1 INTRODUCTION

The variable and transient sky offers a window into the most extreme events that take place in the Universe. Transient phenomena are observed at all wavelengths across a diverse range of objects, ranging from optical flashes detected in the atmosphere of Jupiter caused by bolides (Hueso et al. 2010) to violent Gamma-Ray Bursts (GRBs) at cosmological distances which can outshine their host galaxy (Klebesadel, Strong & Olson 1973; van Paradijs et al. 1997). Observations at radio wavelengths provide a robust method to probe these events, supplying unique views of kinetic feedback and propagation effects in the interstellar medium, which are also just as diverse in their associated time-scales. Active galactic nuclei (AGN; Matthews & Sandage 1963; Smith & Hoffleit 1963) are known to vary over time-scales of a month or longer, whereas observations of the Crab Pulsar have seen radio bursts with a duration of nanoseconds (Hankins et al. 2003).

Historically, and still to this day, radio observations have been used to follow-up transient detections made at other wavelengths. Radio facilities generally had a narrow field of view (FoV), which made them inadequate to perform rapid transient and variability studies over a large fraction of the sky. However, blind transient surveys have been performed and have produced intriguing results. For example, Bower et al. (2007) (also see Frail et al. 2012) discovered a single-epoch millijansky transient at 4.9 GHz while searching 944 epochs of archival Very Large Array (VLA) data spanning 22 years, with three other possible marginal events. Sky surveys using the Nasu Observatory have also been successful in finding a radio transient source, with Niinuma et al. (2007) having observed a two-epoch event, peaking at 3 Jy at 1.42 GHz. Various counterparts were considered at other wavelengths, but the origin of the transient remains unknown. Lastly, Bannister et al. (2011) surveyed 2775 deg^2 of sky at 843 MHz using the Molonglo Observatory Synthesis Telescope (MOST), yielding 15 transients at a 5σ level of 14 mJy beam^{-1} , 12 of which had not been previously identified as transient or variable.

Surveys at low frequencies ($\leq 330 \text{ MHz}$) have also been completed. Lazio et al. (2010) carried out an all-sky transient survey using the Long Wavelength Demonstrator Array (LWDA) at 73.8 MHz, which detected no transient events to a flux density limit of 500 Jy. In addition, Hyman et al. (2002, 2005, 2006, 2009) discovered three radio transients during monitoring of the Galactic Centre at 235 and 330 MHz. These were identified by using archival VLA observations along with regular monitoring using the VLA and the Giant Metrewave Radio Telescope (GMRT). The transients had flux densities in the range of $100 \text{ mJy} - 1 \text{ Jy}$ and occurred on time-scales ranging from minutes to months. Lastly, Jaeger et al. (2012) searched six archival epochs from the VLA at 325 MHz centred on the *Spitzer-Space-Telescope* Wide-Area Infrared Extragalactic Survey (SWIRE) Deep Field. In an area of 6.5 deg^2 to a 10σ flux limit of $2.1 \text{ mJy beam}^{-1}$, one day-scale transient event was reported with a peak flux density of $1.7 \text{ mJy beam}^{-1}$.

Radio transient surveys are being revolutionized by the development of the current generation of radio facilities. These include

new low-frequency instruments such as the International Low-Frequency Array (LOFAR; van Haarlem et al. 2013), Long Wavelength Array (LWA; Ellingson et al. 2013) and the Murchinson Wide Field Array (MWA; Tingay et al. 2013). The telescopes listed offer a large FoV coupled with an enhanced sensitivity, with LOFAR having the capability to reach sub-mJy sensitivities and arcsecond resolutions (though this full capability is not used in this work as such modes were being commissioned at the time.). These features are achieved by utilizing phased-array technology with omnidirectional dipoles, and the above mentioned telescopes act as pathfinders for the low-frequency component of the Square Kilometre Array (SKA; Dewdney et al. 2009). With such greatly improved sensitivities at low frequencies, we have a new opportunity to survey wide areas of the sky for transients and variables, with a particular sensitivity to coherent bursts.

These new facilities have already produced some interesting results in this largely unexplored parameter space. Bell et al. (2014) searched an area of 1430 deg^2 for transient and variable sources at 154 MHz using the MWA. No transients were found with flux densities $> 5.5 \text{ Jy}$ on time-scales of 26 min and one year. However, two sources displayed potential intrinsic variability on a one year time-scale. Using the LWA, Obenberger et al. (2014a) detected two kilojansky transient events while using an all-sky monitor to search for prompt low-frequency emission from GRBs. They were found at 37.9 and 29.9 MHz, lasting for 75 and 100 s, respectively, and were not associated with any known GRBs. This was followed up by Obenberger et al. (2014b) who searched over 11 000 h of all-sky images for similar events, yielding 49 candidates, all with a duration of tens of seconds. It was discovered that 10 of these events correlated both spatially and temporally with large meteors (or fireballs). This low-frequency emission from fireballs was previously undetected and identifies a new form of naturally occurring radio transient foreground.

Two transient studies have now also been completed using LOFAR. Carbone et al. (2015) searched 2275 deg^2 of sky at 150 MHz, at cadences of 15 min and several months, with no transients reported to a flux limit of 0.5 Jy. Cendes et al. (2015) searched through 26, 149-MHz observations centred on the source Swift J1644+57, covering 11.35 deg^2 . No transients were found to a flux limit of 0.5 Jy on a time-scale of 11 min.

In this paper we use the LOFAR telescope to search 400 h of observations centred at the North Celestial Pole (NCP; $\delta = 90^\circ$), covering 175 deg^2 with a bandwidth of 195 kHz at 60 MHz. LOFAR is a low-frequency interferometer operating in the frequency ranges of 10–90 MHz and 110–250 MHz. It consists of 46 stations: 38 in the Netherlands and eight in other European countries. Full details of the instrument can be found in van Haarlem et al. (2013).

A previous study of variable radio sources located near the NCP field ($75^\circ < \delta < 88^\circ$) was carried out by Mingaliev et al. (2009). This study identified 15 objects displaying variability at centimetre wavelengths on time-scales of days or longer. However, the variability amplitude was found to be within seven per cent, which we would not be able to distinguish with LOFAR due to general calibration uncertainties at the time of writing. In addition, the lower

observing frequency used in this work would mean that the expected peak flux densities would be significantly lower, assuming a standard synchrotron event (e.g. van der Laan 1966), making them challenging to detect. Also, the lower frequency means that the variability would occur over even longer time-scales, again assuming that the emission arises from a synchrotron process.

The observations and processing techniques are discussed in Section 2, with a description of how the transient search was performed in Section 3. The results can be found in Section 4, which is followed by a discussion of a discovered transient event in Section 5. The implied transient rates and limits are discussed in Section 6, before we conclude in Section 7.

2 LOFAR OBSERVATIONS OF THE NCP

The monitoring survey of the NCP was performed between 2011 December 23 and 2012 April 16, resulting in a total of 2609 observations being recorded. The NCP was chosen because it is constantly observable from the Northern hemisphere, and the centre of the field is located towards constant azimuth and elevation (*az/el*) coordinates. However, this is not true for sources which lie away from the NCP, where these sources rotate within the LOFAR elliptical beam. We therefore restrict our transient search to an area around the NCP where the LOFAR station beam properties are consistent for each epoch observed, avoiding systematic errors in the light curves that might be introduced if this was not the case. It is also an advantage that the line of sight ($b = 122^\circ.93, l = +27^\circ.13$) is located towards a relatively low column density of Galactic free electrons; the maximum expected dispersion measure (DM) is 55 pc cm^{-3} according to the NE2001 model of the Galactic free electron distribution (Cordes & Lazio 2003).

The NCP measurements were taken using the LOFAR Low-Band Antennas (LBA) at a single frequency of 60 MHz; the bandwidth was 195 kHz, consisting of 64 channels. The total integration time of each snapshot was 11 min, sampled at 1 s intervals, and data were recorded using the ‘LBA_INNER’ setup, where the beam is formed using the innermost 46 LBA antennas from each station, which gives the largest possible FoV and a full width half-maximum (FWHM) of $9^\circ.77$.

2.1 Observation epochs

The programme piggybacked on another commissioning project being performed by LOFAR at the time, the Multifrequency Snapshot Sky Survey (MSSS) – the first major LOFAR observing project surveying the low-frequency sky (Heald et al. 2015). With every single MSSS LBA observation that took place, a beam was placed on the NCP using one subband of the full observational setup for MSSS. Fig. 1 shows a histogram of the number of NCP snapshots observed each day over the duration of the programme, in addition to a similar histogram showing the number of snapshots per hour for a particular set of days. Of the 2609 snapshots, 909 were recorded during the day and 1700 were recorded at night. The MSSS observational set-up also meant that each 11-min snapshot in the same observation block was separated by a time gap of four minutes.

2.2 Calibration and imaging

Before any processing took place, radio-frequency interference (RFI) was removed using `AOFLAGGER` (Offringa et al. 2010; Offringa, de Bruyn & Zaroubi 2012a; Offringa, van de Gronde & Roerdink 2012b) with a default strategy, in addition, the two channels at the highest, and lowest, frequency edges of the measurement set were

Figure 1. Histograms giving a general overview of when the 2609 11-min snapshots of the NCP were observed. The top panel contains a histogram showing how many snapshots were observed on each day over the entire 4 month period, colour coded by month, which shows the distinct observing blocks in which NCP observations were obtained. The bottom panel displays a ‘zoom-in’ of the date range 21:00 2012/02/10–21:00 2012/02/12 UTC, now showing the number of snapshots per hour. This emphasizes further the sometimes fragmented nature of the observing pattern of the NCP, with which careful consideration had to be given on how to combine the observations for the transient search.

also completely flagged, reducing the bandwidth to 183 kHz. When using an automatic flagging tool such as `AOFLAGGER`, it is important to be aware of the fact that transient sources could be mistakenly identified as RFI by the software. This is a complex issue which is beyond the scope of this work. However, an initial investigation for the LOFAR case was carried out by Cendes et al. (2015). In these tests, simulated transient sources, described by a step function, with different flux densities and time durations (from seconds to minutes), were injected into an 11 min data set. These data sets were subsequently passed through `AOFLAGGER` before calibrating and imaging as normal in order to observe how the simulated transient was affected by the automatic flagging, if at all. The authors concluded that transient signals shorter than a duration of two minutes could be partially, or in the case of \sim Jansky level sources, completely flagged. However, there are some caveats to this testing: short time-scale imaging was not tested for short-duration transients, and it remains to be determined how the automatic flagging would treat other types of transients (i.e. a non-step function event). Hence, while these results certainly suggest that transients could be affected by `AOFLAGGER`, further testing is required to completely understand how automatic flagging software can affect the detection of a transient.

At this stage we also removed all data from international LOFAR stations, leaving just the Dutch stations. This was due to the complex challenges in reducing these corresponding data at the time of processing. Following this, the ‘demixing’ technique (described by van der Tol, Jeffs & van der Veen 2007) was used to remove the effects of the bright sources Cassiopeia A and Cygnus A from the visibilities. Finally, averaging in frequency and time was performed such that each observation consisted of 1 channel and an integration time of 10 s per time-step. The averaging of the data was necessary to reduce the data volume and computing time required to process the data.

This averaging has the potential to introduce effects caused by bandwidth and time smearing, which are discussed in more detail by Heald et al. (2015) in relation to MSSS data. Following Heald et al. (2015), we used the approximations given by Bridle & Schwab (1999) to calculate the magnitude of the flux loss (S/S_0) in each case, assuming a projected baseline length of 10 km. We found the bandwidth smearing factor to equal seven per cent (using a field radius corresponding to the FWHM) and a time smearing factor of 0.4 per cent. Thus, while the effect of time smearing was negligible, the impact of bandwidth smearing was potentially significant, yet remained within the calibration error margins (10 per cent; see Section 4.1).

A selection of flux calibrators, characterized by Scaife & Heald (2012),¹ were used in the main processing of the data and were observed simultaneously utilizing LOFAR’s multi-beam capability (thus the calibrator scans were also 11 min in length). The calibrators and their usage can be found in Table 1. The standard LOFAR imaging pipeline was then implemented which consists of the following steps. First, the amplitude and phase gain solutions, using XX and YY correlations, are obtained for each calibrator observation using Black Board Selfcal (BBS; Pandey et al. 2009). These solutions are direction-independent, and are derived for each time step using the full set of visibilities from the Dutch stations, as well as a point source model of the calibrator itself. Beam calibration

Table 1. List of the calibrators used for the NCP observations. It was decided early in the MSSS programme that 3C 48 and 3C 147 might not be adequate as calibrators for the LBA portion of the survey, and so these were dropped 8 and 22 d after first use, respectively. Observations using these calibrators displayed no disadvantages over those observed with other calibrators when checked in this project, and hence they were kept as part of the sample.

| Calibrator source | % use | First use date | Last use date |
|-------------------|-------|----------------|---------------|
| 3C 48 | 2% | 2011 Dec 24 | 2012 Jan 01 |
| 3C 147 | 6% | 2011 Dec 23 | 2012 Jan 14 |
| 3C 196 | 43% | 2011 Dec 24 | 2012 Apr 14 |
| 3C 295 | 40% | 2011 Dec 24 | 2012 Apr 01 |
| Cygnus A | 9% | 2012 Jan 28 | 2012 Apr 16 |

was also enabled which accounts, and corrects, for elevation and azimuthal effects with the station beam. The amplitudes of these gain solutions were then clipped to a 3σ level to remove significant outliers, which were not uncommon in these early LOFAR data. The gain solutions were then transferred directly from the calibrators to the respective NCP observation.

Secondly, a phase-only calibration step was performed (also using BBS) to calibrate the phase in the direction of the target field. The solutions were derived using data within a maximum projected uv distance of 4000λ (20 km; 24 core + 10 remote stations). In order to perform this step, a sky model was obtained of the NCP field using data from the global sky model (GSM) developed by Scheers (2011). This model is constructed by first gathering sources which are present within a set radius from the target pointing in the 74 MHz VLA Low-Frequency Sky Survey (VLSS; Cohen et al. 2007). In the NCP case, the radius was set to 10° . From this basis, sources are then cross-correlated, using a source association radius of 10 arcsec, with the 325 MHz Westerbork Northern Sky Survey (WENSS; Rengelink et al. 1997) and the 1400 MHz NRAO VLA Sky Survey (NVSS; Condon et al. 1998) to obtain spectral index information. In those cases where no match was found, the spectral index, α (using the definition $S_\nu \propto \nu^\alpha$), was set to a canonical value of $\alpha = -0.7$. No self-calibration was performed on the data. The reader is referred to van Haarlem et al. (2013) for more LOFAR standard pipeline information.

The main MSSS project discovered that observations recorded during this 2011–2012 period potentially contained one or more bad stations, and the data quality would improve if such stations were removed. LOFAR was still very much in its infancy at the time, and, as a result, was not entirely stable; problems such as network connection issues or bad digital beam forming contributed to the poor performance of some stations. Hence, an automated tool was developed which analysed each station, identifying and flagging those that displayed a significant number of baselines with high measured noise. This tool was utilized in the NCP processing and primarily removed stations with poorly focused beam responses (Heald et al. 2015). It should be noted that present LOFAR data no longer require this tool as the issues outlined above have been rectified.

Finally, an FoV of 175 deg^2 was imaged using the `AWIMAGER` (Tasse et al. 2013), with a robust weighting parameter of 0 (Briggs 1995), and a primary-beam (PB) correction applied to each image. A maximum projected baseline length of 10 km was used in this study (2000λ ; 24 core + seven remote stations). This was chosen to obtain good uv coverage and a maximum resolution for which we were confident with the calibration. The typical resolution for the 11-min snapshots was $5.4 \times 2.3 \text{ arcmin}$.

¹ Cygnus A is not characterized by Scaife & Heald (2012), but extensive commissioning work (summarized by McKean et al. 2011 and McKean et al., in preparation) has produced a detailed source model.

2.3 Quality control

A number of bad-quality observations were detected and subsequently flagged using two methods: (i) checking the processed visibilities and (ii) inspecting the final images for each 11-min snapshot. When analysing the visibilities, poor snapshots were flagged when the calibrated visibilities had a mean value greater than the overall mean of the entire four month data set plus one standard deviation value. A slight, or indeed dramatic, rise in the mean of the visibilities does not necessarily imply a completely bad data set: an extremely bright transient (>100 Jy) could have this effect, for example. Such events may have been previously seen from flare stars at low frequencies (Abdul-Aziz et al. 1995), although at shorter time-scales than 11 min (~ 1 s). However, overall, the survey is less sensitive to extremely bright events because of this quality control step. It was beyond the scope of this project to fully investigate this possible effect, and so we decided to only use measurement sets that were deemed to be sufficiently well calibrated.

The results from the automated flagging were also checked against a manual analysis of the visibility plots and the snapshot images, the latter enabling the detection of more bad observations. In total, 460 (out of 2609) snapshots were marked as bad, and were discarded from the search. The large size of the full data set meant that there was no single common reason as to why individual snapshots were rejected, but the problems that caused rejection were mostly due to RFI or ionospheric issues. After the quality control was completed, 2149 observations (394 h) were considered in the analysis.

3 TRANSIENT AND VARIABILITY SEARCH METHOD

3.1 Time-scales searched

As the properties of the target transient population are unknown, the complete data set was split and combined in various ways to fully explore the transient parameter space available. Along with performing a search on the original snapshots, each with an integration time of 11 min, searches were also performed on images with integration times of 30 s, 2 min, 55 min and 297 min. For the longer-duration images, only those 11-min snapshots which were four minutes apart were combined together and imaged. This was to keep the visibilities as continuous as possible in the search for transients. After the quality control step described in Section 2.3, 297 min was the longest continuous integration time possible. All calibration was performed on each individual 11-min snapshot; for the longer time-scales the relevant data sets were combined and then imaged.

3.2 The transients pipeline

The analysis of the data and search for radio transients were performed using software developed by the LOFAR Transients Key Science Project, named the Transients Pipeline (TRAP). It is built to search for transients in the image plane, whilst also storing light curves and variability statistics of all detected sources. Moreover, it is designed to cope with large data sets containing thousands of sources such as this NCP project. A full and detailed overview of the TRAP can be found in Swinbank et al. (2015).² In brief it performs the following steps:

² The work presented in this paper primarily used TRAP release 1.0. However, the data were re-processed once TRAP release 2.0 was available, which is the version described by Swinbank et al. (2015), to confirm results.

Table 2. The average image sensitivity and number of epochs for each time-scale at which a transient search was performed. The accepted epochs column defines how many of the total number of images passed the TRAP image quality control.

| Time (min) | Average rms (mJy beam ⁻¹) | Typical resolution (arcmin) | Total no. of epochs | Accepted no. of epochs |
|------------|---------------------------------------|-----------------------------|---------------------|------------------------|
| 0.5 | 3610 | 4.8×2.2 | 47 970 | 41 340 |
| 2 | 2110 | 4.7×2.1 | 10 739 | 9 262 |
| 11 | 790 | 5.4×2.3 | 2 149 | 1 897 |
| 55 | 550 | 4.9×2.1 | 371 | 328 |
| 297 | 250 | 3.1×1.4 | 34 | 32 |

(i) Input images are passed through the TRAP quality control which examines two features of the images. First, the rms of the map is compared against the expected theoretical rms of the observation, and if the ratio between the observed and theoretical rms is above a set threshold then the image is flagged as bad. In this case, the threshold was set to the mean ratio value of each time-scale plus one standard deviation. The second test involves checking that the beam is not excessively elliptical by comparing the ratio of the major and minor axes. If this value is over a set threshold then the image is also flagged as bad. All bad images are then rejected and are not analysed by the TRAP (see Rowlinson et al., in preparation for methods of setting these thresholds). The number of images accepted by the TRAP compared to the total entered can be seen in Table 2.

(ii) Sources are extracted using PYSE – a specially developed source extractor for use in the TRAP (Spreeuw 2010, Carbone et al., in preparation). Importantly, all sources are initially extracted as unresolved point sources, which would be expected from a transient event.

(iii) For each image, the source extraction data are analysed to associate each source with previous detections of the same source, such that a light curve is constructed. In cases where no previous source is associated with an extraction, the source is flagged as a potential ‘new source’ and is continually monitored from the detection epoch onwards.

For the source extraction, we define an island threshold, which defines the region in which source fitting is performed, and a detection threshold where only islands with peaks above this value are considered. These island and detection thresholds were set to 5σ and 10σ , respectively. While the use of a 10σ detection threshold may seem very conservative, we agree with the arguments presented by Metzger, Williams & Berger (2015) (hereafter MWB15) who advocate these criteria when identifying a transient source. In their paper, the authors’ main motivation for this high threshold is the significant possibility of spurious signals such as those seen in previous radio transient searches (Gal-Yam et al. 2006; Ofek et al. 2010; Croft et al. 2011; Frail et al. 2012; Aoki et al. 2014), arising from calibration artefacts, residual sidelobes and other similar issues. We share these concerns, in addition to being generally cautious as this survey is one of the first conducted with the new LOFAR telescope. As also stated by MWB15, previous surveys have used 5σ as a detection threshold, which will of course increase the number of potential transient detections; however, this will also yield a high number of false detections, especially with the large number of epochs being used in this survey. Thus, minimizing false detections and obtaining a manageable number of transient candidates were further motivations to use a 10σ detection threshold. We refer the reader to MWB15 for further discussion on this topic.

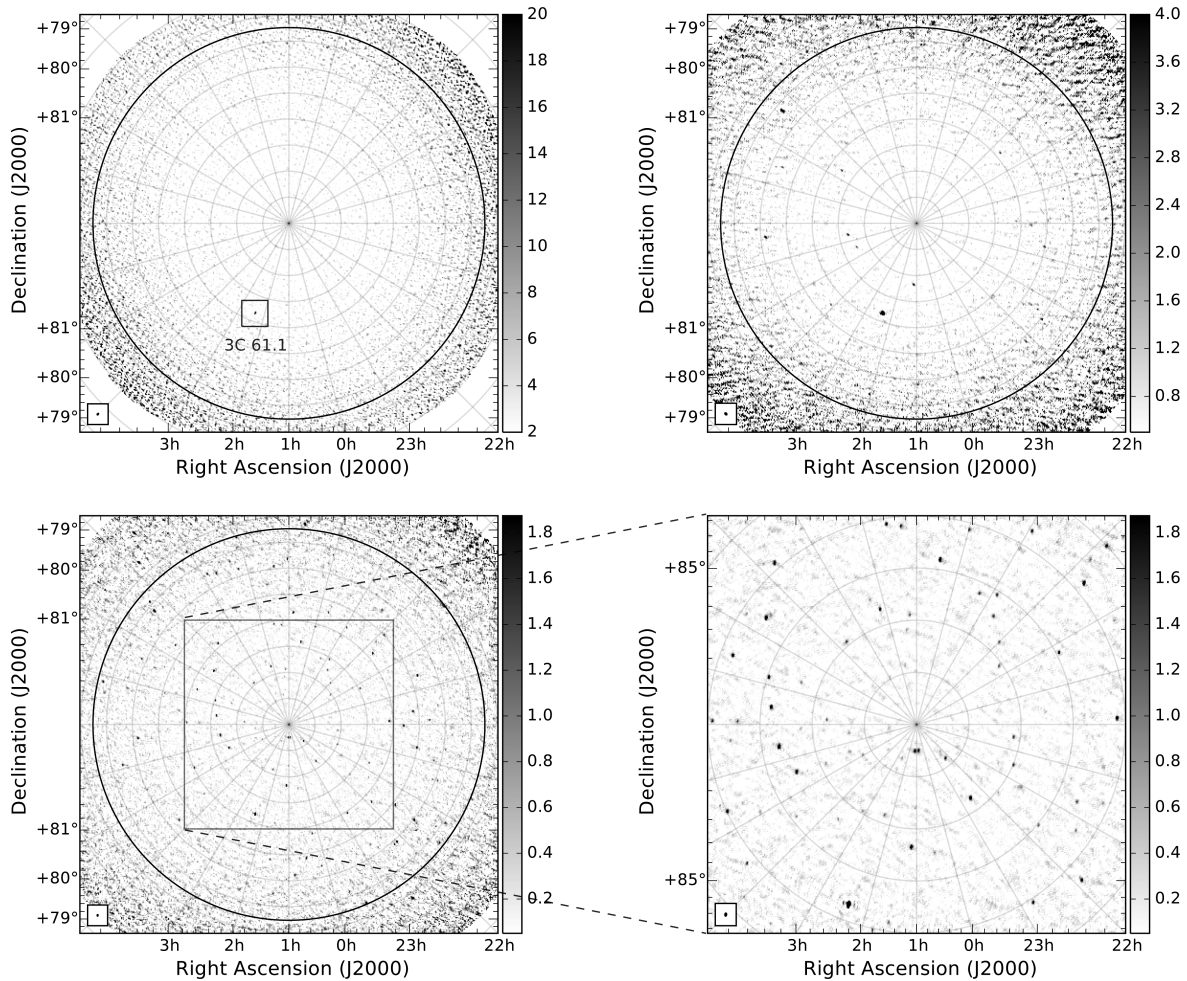

Figure 2. Examples of the NCP field maps at different time-scales. Where present, the area within the black circle indicates the portion of the image searched for transients. This was the same for each time-scale and had a radius of 7.5 . Upper left panel: an image on the 30 s time-scale which was observed on 2012 January 9. Using projected baselines of up to 10 km, the map has a resolution of 4.2×2.3 arcmin (synthesized beam position angle [BPA] -39°) with a noise level of 1.9 Jy beam^{-1} . Only the source 3C 61.1 is detected at a 10σ level, and this source is marked on the image. Upper right panel: an 11 min snapshot observed on 2011 December 31. The noise level is $320 \text{ mJy beam}^{-1}$ and the resolution is 5.6×3.6 arcmin (BPA 43°). The number of detected sources at a 10σ level is now ~ 15 . Lower left panel: an example of the longest time-scale images available of 297 min, constructed by concatenating and imaging 27, 11-min sequential snapshots. Observed on 2012 February 4, this image has a resolution of 3.5×2.0 arcmin (BPA -6°) and a noise level of $140 \text{ mJy beam}^{-1}$, with ~ 50 sources now detected at a 10σ level. Lower right panel: a magnified portion of the lower left panel image. The colour bar units are Jy beam^{-1} .

The transient search was also constrained to within a circular area of radius 7.5 from the centre of the image. This was to avoid the outer part of the image which was much noisier and did not have reliable flux calibration.

For each light curve, two values are calculated in order to define whether a source is a likely transient or variable: V_v , a coefficient of variation, and η_v , the significance of the variability (Scheers 2011). V_v is defined as

$$V_v = \frac{s_v}{\bar{I}_v} = \frac{1}{\bar{I}_v} \sqrt{\frac{N}{N-1} (\overline{I_v^2} - \bar{I}_v^2)}, \quad (1)$$

where s is the unbiased sample flux standard deviation, \bar{I} is the arithmetic mean flux of the sample, and N is the number of flux measurements obtained for a source. The significance value, η_v , is based on reduced χ^2 statistics and indicates how well a source light curve is modelled by a constant value. It is given by

$$\eta_v = \frac{N}{N-1} \left(\frac{\omega \overline{I_v^2}}{\bar{\omega}} - \frac{\bar{\omega} I_v^2}{\bar{\omega}} \right), \quad (2)$$

where ω is a weight which is inversely proportional to the error of a given flux measurement ($\omega = 1/\sigma_{I_v}^2$). Throughout this paper we define these parameters as the ‘variability parameters’. For more detailed discussion on these parameters we refer the reader to Scheers (2011) and Swinbank et al. (2015).

To define a transient or variable source, a histogram of each parameter for the sample was created and fitted with a Gaussian in logarithmic space. Any source which exceeds a 3σ threshold on these plots is flagged as a potential candidate. Rowlinson et al. (in preparation) will offer an in-depth discussion on finding transient and variable sources using these methods.

4 RESULTS

4.1 Image quality

Examples of the 30 s, 11 min and 297 min time-scale images can be found in Fig. 2. Note that imaging the NCP can sometimes cause confusion when displaying the right ascension (RA) and declination

Figure 3. Left panel: the uv coverage obtained with an 11 min snapshot. Right panel: the improved uv coverage gained when combining 27 snapshots (297 min). In each case the uv range is limited to ± 2 $k\lambda$ (10 km).

(Dec) on the image axis, as the grid lines become circular. The grid lines are shown in all figures to help demonstrate this. The obtained uv coverage of the 11 and 297 min observations can be viewed in Fig. 3. The average sensitivity reached with each time-scale is summarized in Table 2, along with the number of epochs available after the quality control described in Sections 2 and 3.

It is important to note that, as a consequence of the PB correction, search areas centred on the NCP do not have a uniform noise level. Larger search areas include noisier regions further from the phase centre, and hence the flux density threshold at which we could detect a transient across the full search area will be higher. Fig. 4 shows an example of a PB map from one of the NCP observations. In order to obtain a noise estimate accounting for the variation caused by the beam, for each image at each time-scale we split the area into four annuli, equally spaced in radius. These four regions are also marked in Fig. 4. The rms for each annulus was then measured, using a clipping technique, with the area-weighted average of these four values providing the single value rms estimate for the individual image. We then took the average of each time-scale, which are used as our sensitivity levels in Table 2. Fig. 5 shows that these measured rms values of the different time-scales approximately follow a $1/\sqrt{t}$ relation, where t represents the integration time of the observation. We note that the longer time-scale rms values appear to lie above the $1/\sqrt{t}$ relation. We believe this is caused by the clipping technique being less accurate at measuring the rms of the longer time-scale images annuli. This in itself is due to the presence of many more sources compared to the relatively source free-short time-scale images. In addition to this, it is possible that the CLEAN algorithm was not applied to a deep enough level in some cases. Hence, the combination of these two methods means that the longer time-scale rms values are likely to be slightly overestimated, but not at a concerning level in the context of this investigation.

We could have limited the transient search to a smaller region with the deepest sensitivity; however, when calculating the figure of merit (FoM; $\propto \Omega s^{-3}$ where Ω is the FoV and s is the sensitivity) it can be shown that it is more beneficial to extend the area of

Figure 4. An example of a normalized PB map from one of the NCP observations, which has been scaled to 1.0. The bold, outer solid-line circle represents the full extent of the area for which the transient search was performed (radius of 7.5). The inner solid-line circles show how the area was divided in order to gain an estimate of the average rms for each image accounting for the PB. The dashed-line circle indicates the position of the PB half-power point.

the search, despite the increase in average rms. This can easily be demonstrated as the full area is 16 times larger but the weighted sensitivity only drops by a factor of about 2; hence the FoM is around five times better, illustrating the motivation for searching wide area. We refer the reader to Macquart (2014) for an in-depth discussion of the FoM in the context of transient surveys.

Figure 5. The average rms obtained from the images produced by combining and splitting the data set. Also plotted in light grey are the range of noise values for the individual images at their respective time-scales, in addition to the $1/\sqrt{t}$ relation where t is the integration time of the observation. It can be seen that the average rms values approximately follow this relation; the longer time-scale values are likely to be slightly overestimated due to the methods used to estimate the rms. The errors shown on the average points are one standard deviation of the rms measurements from the respective time-scale.

Figure 6. Plot of the mean extracted flux of sources from the 297 min NCP survey at 60 MHz against the cross-matched VLSS survey at 74 MHz. The solid line represents the expected LOFAR flux density assuming a spectral index of $\alpha = -0.7$. For illustrative purposes a dashed-line representing $\alpha = 0$ (a 1:1 ratio) is also shown.

The 55 and 297 min time-scale images offered the best flux calibration stability from image to image due to the better uv coverage achieved on these time-scales. An example of the general flux calibration quality can be seen in Fig. 6, which shows the averaged measured flux across all the 297 min snapshots of sources detected at 60 MHz, cross-matched with the VLSS catalogue at 74 MHz. It shows a general agreement with the fluxes that would be expected assuming an average spectral index of $\alpha = -0.7$. If we assume that all sources have this spectral index and calculate the expected VLSS 60 MHz flux for each source, we find that the average ratio of this expected VLSS flux against the measured LOFAR flux is 1.00 ± 0.17 .

Overall, there was a typical scatter of 10 percent in each light curve of sources detected, which was measured by the `TRAP`. It was common that fainter sources ($<10\sigma$) would appear to ‘blink’ in and out of images; this was especially apparent in the 11 min snapshots. This was likely due to a mixture of varying rms levels and the ionosphere causing phase calibration issues. Such behaviour was a further reason why a 10σ source detection limit was used in the transient search. The sensitivities of the shortest time-scale maps, 30 s and 2 min, were such that only the brightest source in the field, 3C 61.1, was detectable. The LOFAR and VLSS source positions were also consistent within 5.1 arcsec on average; the typical resolution in the LOFAR band is 3.1×1.4 arcmin for the 297 min time-scale.

It was also important to determine whether the images produced for the transient search are confusion limited. In order to calculate an estimate of the confusion noise for the average resolutions presented in Table 2, we followed the same approach as Heald et al. (2015), using VLSS C-configuration estimates (see Cohen 2004) which we extrapolate to 60 MHz using a typical spectral index of -0.7 . We also alter the formula to account for the non-circular beams:

$$\sigma_{\text{conf, VLSS}} = 29 \left(\frac{\theta_1 \times \theta_2}{1''} \right)^{0.77} \left(\frac{60 \text{ MHz}}{74 \text{ MHz}} \right)^{-0.7} \mu\text{Jy beam}^{-1}, \quad (3)$$

where θ_1 is the synthesized beam size major axis and θ_2 is the minor axis. For the five time-scales used in the transient search shown in Table 2, beginning with 30 s, we calculate the confusion noise estimates to be 113, 107, 128, 111 and 57 mJy beam $^{-1}$, respectively. Thus, due to our simple reduction strategy, our images, at best, are approximately 4 times the confusion noise level and hence would not affect our transient search.

Along with these cadences, a deep map was constructed by using all the available 297 min images, reaching a sensitivity of 71 mJy beam $^{-1}$ (this value was measured using the weighted average method discussed above in this section.). This map can be seen in Fig. 7. This, however, had to be produced by means of image stacking as opposed to direct imaging due to the amount of data involved. A total of 150 sources were detected at a 10σ level within the same $7:5$ radius circle used for the transient search, with the map primarily being used as a deep reference image for the field. We can, however, use this deep map to verify our calibration and imaging procedures by comparing our detected source counts to the VLSS. First, using a spectral index of -0.7 , $S_{60} = 710$ mJy corresponds to a flux density at 74 MHz of $S_{74} = 613$ mJy. Using this flux density limit, there are 263 catalogued VLSS sources within $7:5$ of the phase centre. Cross-correlating the VLSS with our LOFAR 60 MHz detections, we find that 41 percent of the VLSS sources have a LOFAR match. The factor of ~ 2 discrepancy can be shown to be simply due to the PB attenuation in our deep map. Hence, we were satisfied that the calibration and imaging results were valid and consistent with previous studies, and therefore would not negatively impact any transient searches.

This map was also further analysed for any previously uncatalogued radio sources, but none were found. However, the direct comparison to VLSS revealed that one source, located at $02^{\text{h}}13^{\text{m}}28^{\text{s}}+84^{\circ}04'18''$, has apparently significantly different 60 and 74 MHz flux densities: the VLSS-integrated flux density is 1.49 Jy (possibly put in the error), whereas in the LOFAR band it is detected at the 8σ level with an integrated flux density of 236 mJy. There are no detections of the source in WENSS or NVSS. However, this source is located within a stripe feature in the VLSS image, and the

Figure 7. The deepest map produced of the NCP field from the survey. It was constructed by averaging all 31 of the 297-min-duration images together in the image plane, using inverse-variance weighting. It has a noise level of 71 mJy beam^{-1} and a resolution of $3.1 \times 1.4 \text{ arcmin}$ (BPA 42°). A total of 150 sources are detected at a 10σ level within a radius of 7.5 from the centre of the map. While none of these sources are previously undetected, it provided a detailed reference map to check any transient candidates. The colour bar units are Jy beam^{-1} .

source is not present in the VLSS Redux catalogue (VLSS; Lane et al. 2014); hence we do not pursue this source further. The full MSSS survey will offer further insight into this potential source, confirming its flux density and spectral index, if it is real.

4.2 Variability search results

The four month data set provides an opportunity to search for variable sources as well as transient sources. We define variables as sources which are present throughout the entire data set, taking into consideration varying sensitivity, whose light curve displays significant variability over the period. This is opposed to transient sources, which we define as sources that appear or disappear during the time spanned by the data set, again taking into account the varying sensitivity. Consulting historical catalogues also helps with the distinction between variables and transients. Due to the higher level of image quality, the variability search was limited to the two longest time-scales of 55 and 297 min. For each detected source in these two sets of images, variability parameters (V_v and η_v) were calculated by the TRAP. Fig. 8 shows the respective distributions of the variability parameters for each time-scale plotted in logarithmic space. In each case, the central panel shows η_v plotted against V_v for each detected source. The top panel displays a histogram representing the distribution of η_v of all the sources along with a fitted Gaussian curve. The right panel contains the distribution and fitted Gaussian curve for V_v . The dashed lines represent a 3σ threshold for each value; any sources with variability parameters exceeding one or both of these values are considered as potentially variable. Candidates also had to show a variability of significantly more than 10 per cent, which was the calibrator error of the measurements. This was set at a level of 2σ from this value. An ideal transient would appear in the top-right-hand corner of the central panel scatter plot, exceeding the threshold in each parameter.

Figure 8. This figure shows the distribution of values obtained for the variability parameters V_v , a coefficient of variation, and η_v , the significance of the variability (see text for full definitions) for each light curve detected. The upper panel shows the 55-min image results and the lower panel shows the 297-min time-scale results. In each case, the central panel plots the two values against each other for each source, with the top panel and right side panel displaying the histogram showing the distribution of the η_v and V_v values, respectively, for all sources. The dotted lines represent a 3σ threshold for each parameter. A very likely variable or transient source would appear in the top-right of the plot, exceeding a 3σ level in each parameter. At both time-scales, one source (3C 61.1) is found to have a significant value in η_v . However, this is likely to arise from fluctuations caused by calibration issues.

It can be seen that at both time-scales, no sources exhibit variable behaviour in V_v above a 3σ level, but one source has a significant η_v value. This source is 3C 61.1, which dominates the field. While the result points towards low-level variability of 3C 61.1, the source is a well-resolved radio galaxy (Leahy & Perley 1991) whose flux

is dominated by 100-kpc-scale lobes, making it very unlikely that we would detect any intrinsic variability. It is more likely that this is the result of calibration errors and the source extraction and subsequent calculation of η_v itself. The model for 3C 61.1 used during this investigation is quite basic for such a complex source. This, along with ionospheric effects and the general calibration accuracy of the instrument at the time, can have quite a substantial effect on such a bright source, with such calibration errors not included in this analysis. The source is also spatially extended, but the extraction treats it as a point source (as mentioned in Section 3), and this will therefore also have a significant impact on the recorded flux. Removing the point source fitting constraint does indeed move the data point closer back towards the 3σ threshold, but only marginally by 0.1 dex in η_v . As for the η_v value, this parameter is weighted by the flux errors of the source extraction. Bright sources, such as 3C 61.1, are well fitted when they are extracted, which means they have small associated statistical flux errors. This in turn then causes η_v to rise. If we discount 3C 61.1, no sources displayed any significant variability at the 55 and 297 min time-scales.

4.3 Transient search results

Using the TRAP and a manual analysis of its results, searches performed on the time-scales of 0.5, 2, 55 and 297 min found no transient candidates. However, nine transient candidates emerged from the analysis of the 11-min time-scale. At first, it appeared strange to achieve nine candidates at one time-scale but none at any other. However, the sensitivity of the shorter time-scales was such that only bright transients (>25 Jy) would have been confidently detected, and as previously stated no other source, or even artefact, was detected at these flux levels other than 3C 61.1. At the longer time-scales, the improved uv coverage meant that the images improved substantially in quality. This reduced the number of imaging artefacts that could spawn false detections and sources were consistently detected throughout the epochs (as opposed to many sources blinking in and out as discussed in Section 4.1). Any sources that were defined as ‘new’ by the TRAP (these are sources that appeared in later images but were not detected in the first image searched) were in fact association errors and not transient sources.

While the nine candidates could point towards the 11 min images meeting the required sensitivity and time-scale of a transient population, these images are also the most likely to exhibit misleading artefacts due to the limited uv coverage. Hence, the nine reported candidates were subjected to a series of tests to determine whether they were spurious sources. The following tests were performed:

- (i) Subtraction of 3C 61.1 from the visibilities using the clean component model from the deconvolution process. The visibilities were then re-imaged.
- (ii) Applying an extra round of RFI removal using AOFLAGGER.
- (iii) Re-running the automated tool to remove perceived bad LOFAR stations from the observations, followed by a manual check.
- (iv) Imaging the data using different weighting schemes and baseline cutoffs.

The tests were applied in the above order, meaning that if one method definitely succeeded in removing the candidate the latter tests were not performed. Only one of the nine candidates completely survived all the tests; three were inconclusive but quite doubtful, whereas four were definite artefacts. One other source was very marginal in passing all the tests; hence this event is not presented in this paper, but will be discussed in a future publica-

tion. The surviving candidate was thus a potential real astrophysical event and is the subject of the following Section 5.

5 TRANSIENT CANDIDATE ILT J225347+862146

The only candidate to have passed all the validity checks was found in a single 11 min snapshot taken on 2011 December 24 at 04:33 UTC. The source was extracted by the TRAP with a flux of 7.5 Jy (14σ detection in individual image), at coordinates $22^{\text{h}}53^{\text{m}}47^{\text{s}}.1+86^{\circ}21'46''.4$, with a positional error of 11 arcsec. It was only seen in this one snapshot with no detection of the source in the preceding or subsequent snapshots. The observation can be seen in Fig. 9. Nothing was present at the candidate position in either the relatively deep image constructed from the longer time-scale images (see Section 4.1) or the very deep image of the field from the LOFAR Epoch of Reionization (EoR) group (Yatawatta et al. 2013). Note that the EoR project uses the LOFAR high-band antennas, and hence it is at a higher frequency range of 115–163 MHz.

5.1 A mirrored ghost source

On closer inspection, the transient candidate appeared to have a secondary-associated positive ‘ghost’ source mirrored across the brightest source in the field, 3C 61.1 (the transient lies at an angular distance of $3^{\circ}2'$ from 3C 61.1.), which can also be seen in Fig. 9. This ghost was not detected by TRAP due to the higher rms value in that region, and like the transient candidate it was a ‘new’ source with no previous or subsequent detections. In fact, the ghost source was actually nominally brighter than the transient source with a flux density of 13 Jy. However, in the non-PB-corrected map the candidate has a higher peak flux density (9 Jy) than the ghost (6 Jy). This was not the first time we had witnessed this type of effect in LOFAR observations, with previous commissioning data we had obtained in 2010 showing a similar situation. Currently, the exact explanation of why ghosts of this nature, including specifically the ghost presented in this work, are generated in LOFAR data is unknown. It should be noted that none of the other eight transient candidates detailed previously had an associated ghost source. In the following discussions we refer to the original detected transient source ILT J225347+862146, to the west of 3C 61.1, as the ‘transient candidate’ and the source to the east of 3C 61.1 as the ‘ghost’ source (refer to Fig. 9).

5.1.1 Ghost artefacts in radio interferometry

Calibration artefacts presenting themselves as spurious ‘ghost’ sources are not an entirely new topic to radio interferometry. The topic of ‘spurious symmetrization’ is discussed in Cornwell & Fomalont (1999); in brief, if a point source model is used for a slightly resolved source, a single iteration of self-calibration can result in features of the image being reflected relative to the point-like object. However, this can be corrected with further iterations of self-calibration which would cause the spurious features to disappear. As will be discussed in Section 5.1.2, the ghost presented in this work can be seen before initiating any kind of self-calibration of the target field, i.e. any calibration using a target field sky model. Therefore, it is highly unlikely that the spurious symmetrization previously described is the sole cause of the ghost. However, this is not to say that the effect plays no role in its creation.

More recently, Grobler et al. (2014) (hereafter ‘G14’) began a series of investigations dedicated to ghost phenomena. This first study

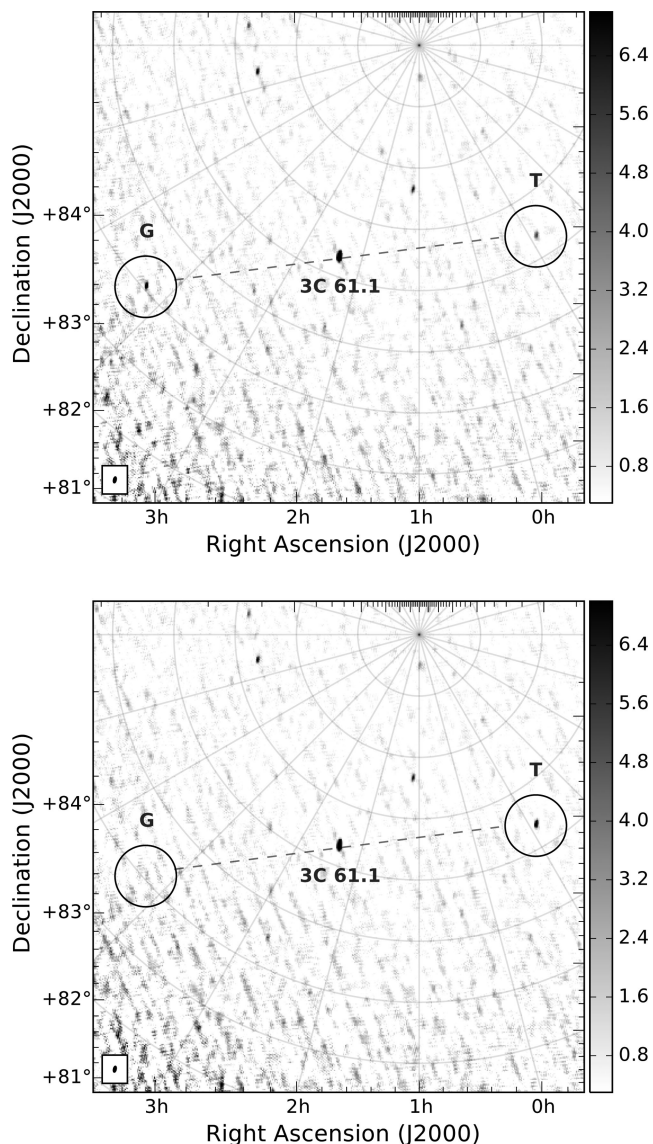

Figure 9. Upper panel: illustration of how the transient source (labelled ‘T’), ILT J225347+862146, was originally detected in the image, along with the associated ghost source (labelled ‘G’) across from 3C 61.1. Lower panel: now the measurement set as been re-calibrated with the transient included in the sky model; the ghost source has vanished. Upon closer inspection, other faint, source-like features also disappear from the re-calibrated image. These are most likely fainter ghost features which are reduced when the data were calibrated with a more complete sky model. The colour bar units are Jy beam^{-1} .

concentrated on ghosts seen in data from the Westerbork Synthesis Radio Telescope (WSRT). In these data, ghost sources appeared as strings of (usually) negative point sources passing through the dominant source(s) in the field. The arrangement of these negative point sources appeared quite regular, along with the fact that the positions were not affected by frequency. In their investigation, G14 were successful in deriving a theoretical framework to predict the appearance of ghosts in WSRT data for a two-source scenario, and were able to confirm what previous work had suggested concerning these ghost sources (see text in G14).

In brief, the main features about ghosts to note are as follows: (i) they are associated with incomplete sky models, for example missing or incorrect flux; (ii) in the WSRT case, the ghosts always

formed in a line passing through the poorly modelled or unmodelled source(s) and the dominant source(s) in the field; (iii) the ghosts are mostly negative in flux, while positive ghosts are rare and weaker; and (iv) the general ghost mechanism can also explain the observed flux suppression of unmodelled sources.

G14 also concluded that the simple East–West geometry of the WSRT array is the reason for ghosts appearing in a regular, straight line, pattern. This becomes more complex when a fully 2D/3D array is considered such as LOFAR, where the ghost pattern is expected to become a lot more scattered and noise-like. This subject will be the focus of Paper II (Wijnholds et al., in preparation) in the series on ghost sources. However, G14 did note that regardless of the array geometry, ghosts are expected to occur at the $n\phi_0$ positions, where ϕ_0 represents the angular separation between the respective bright source and unmodelled source, and n is an integer number. Usually the strongest ghost responses are the $n = 0$ and $n = 1$ positions, i.e. the suppression ghosts that sit on top of the sources in question. However the case discovered in this work, and also two independent cases (de Bruyn, private communication; Clarke, private communication) in LOFAR data suggest that the $n = -1$ position could also generate a strong response. What is significant about the transient presented in this work, however, is that the ghost appears as a positive source.

5.1.2 Investigating the NCP ghost

Returning to the situation detailed in this paper, we were presented with two sources for which either could be the real (transient) source or the ghost. We attempted to simulate the situation within real data, in order to investigate how the different stages of calibration would react to a bright transient, and if we could also generate a positive ghost source. This was done by taking a different NCP observation and inserting a simulated transient source into the visibilities (the transient was set to be ‘on’ for the entire 11 min.) before any calibration had taken place. The snapshot was then calibrated as normal, but importantly the inserted source was *not* included in the NCP sky model used for the phase-only calibration step (refer to Section 2.2). This test was repeated using various different sky positions and flux densities for the inserted source. We found that we could produce a significant positive ghost source only if the flux of the simulated transient was relatively bright, ~ 40 Jy. An example can be seen in Fig. 10. We observed that it was common for the total flux to be shared approximately equally between the simulated source and its associated ghost. However, not every position on the sky at which the transient was inserted produced a ghost source, a feature that we cannot currently explain. Yet, when a transient was inserted at the position of ILT J225347+862146, this did produce a ghost source. We were then able to test what happened when the simulated source was included in the sky model. We observed that when the simulated source was accounted for perfectly in the sky model, the ghost source disappeared. If the sky model component was instead inserted at the location of the ghost source, while the ghost appeared brighter, the simulated transient never fully disappeared.

In light of the results from the simulations, we performed the same sky model test with the transient candidate and ghost in order to determine which source was the ‘real’ source. Recalling that the total flux of the transient candidate and ghost was ~ 7 Jy + ~ 13 Jy ≈ 20 Jy, we began by inserting a 20 Jy point source into the NCP sky model at the position of the transient candidate and re-calibrated the data set. We found that in this case the flux of the ghost was significantly reduced, by ~ 70 per cent, and the candidate

Figure 10. The resultant image after a simulated transient source (labelled ‘ST’) was inserted into the visibilities of a NCP observation and processed without the simulated source in the sky model. A ghost source (labelled ‘G’) appears mirrored across 3C 61.1. The effect is not limited to one specific insertion point of the simulated transient and is more pronounced the brighter the simulated transient. In this example, a source of brightness 80 Jy was inserted, which produces a very significant ghost source. The simulated transient and ghost source each had a measured flux density of ~ 25 Jy, with the remaining ~ 30 Jy being absorbed by 3C 61.1. This transfer of flux was common when the simulated transient was brighter than 3C 61.1 (~ 80 Jy). When lower, the flux is shared equally between the simulated and ghost sources, with minimal flux transferred to 3C 61.1. The colour bar units are Jy beam^{-1} .

brightened by ~ 100 per cent. Alternatively, if the model component was entered at the ghost location, the candidate source and ghost respective fluxes were only ~ 10 per cent different from their initial fluxes on discovery, i.e. when they were not in the sky model at all. In fact, increasing the sky model component to 25 Jy and placing it back at the position of the transient candidate reduced the ghost such that it was no longer distinguishable from the noise, as seen in the bottom panel of Fig. 9. Hence, the ‘real’ source was determined to be at the position TRAP had originally reported, $22^{\text{h}}53^{\text{m}}47^{\text{s}}.1 + 86^{\circ}21'46''.4$, to the west of 3C 61.1.

The above tests have concentrated on the target NCP field sky model, but we also have the sky model which was used to calibrate the calibrator observation. For this observation, the calibrator source was 3C 295. Considering that ghosts occur because of sky model errors, one could envision a scenario in which the error being transferred from the calibrator to the target field results in the ghost pattern observed. As mentioned in Section 2.2, the calibrator sky models only contain the calibrator source itself and not any surrounding field sources. While this generally allows the derivation of sufficiently accurate gain solutions, the missing flux could be attributed to a ghost pattern, which is then transferred to the target field (see also Asad et al. 2015 for a similar discussion regarding the 3C 196 field).

To investigate this, two tests were performed. First, the phase-only calibration step was ignored and we imaged the data set using the amplitude and phase gain solutions directly from the calibrator. In this case, both the transient and the ghost were present, with no major changes from before (a result which makes ‘spurious sym-

metrization’, previously discussed in Section 5.1.1, unlikely to be the sole cause of the ghost). Secondly, the calibrator observation was not used at all and instead the data were calibrated in both amplitude and phase using the constructed NCP target sky model (described in Section 2.2) which importantly did *not* contain the transient source. For this test, we increased the solution interval to one minute (originally 10 s) to gain more signal-to-noise ratio for the calculations. We also had to perform post-processing clipping to the visibilities to eliminate bad amplitude spikes in the calibrated visibilities. In the full 11-min image, while the rms rose to ~ 800 mJy beam^{-1} , a source was detected within 1 arcmin (the resolution of the image was 5.6×2.4 arcmin.) of the reported transient candidate position with a flux density of 13 Jy. The ghost source was not detected to a 5σ limit of 10 Jy at its expected location, nor was it visible when the map was manually inspected. However, due to the increase of the rms in this case, we cannot state with complete confidence that the ghost source is not present at all. Nonetheless, observing the transient source without placing it in the sky model provided additional evidence that we had identified the correct source.

The above result tentatively points to the calibrator having an important role in the ghost creation. However, understanding the exact ghost mechanism is a complex task in the LOFAR case, and each stage of the calibration must be taken into careful consideration. For example, G14 has exclusively investigated situations where full amplitude and phase calibration is used, so the effects of a phase-only calibration are generally unknown at this stage. At the time of writing, we cannot explain how the ghost is generated; a detailed investigation is under way (Grobler et al., in preparation) to resolve the matter.

5.2 Transient flux density

5.2.1 Obtaining the correct flux

The correct flux density of the transient proved difficult to ascertain. We attempted to obtain an estimate by entering flux values of the transient source manually into the calibration sky model, over a range of 7.5–45 Jy, in steps of 2.5 Jy, and proceeded to recalibrate the visibilities (as previously described, this calibration step is phase only.). We then observed the influence this had on the measured flux density of the transient itself, as well as the measured flux densities of the surrounding sources, including the ghost source. We remind the reader that the transient candidate, the source deemed ‘real’, is to the west of 3C 61.1 and the ghost is the source to the east of 3C 61.1. The transient was always placed as a point source in the sky model. The results of this experiment can be seen in Fig. 11. We found that the ghost source became increasingly fainter as the transient flux was increased, right up until the transient was entered as 20 Jy and the ghost could no longer be distinguished from the background. The transient ‘light curve’ itself follows the trend of the increasing sky model flux, but it also exhibits a sudden local maximum when the sky model entry level is changed from 22.5 to 25 Jy. In this instance, the extracted flux rises from 16 to 20 Jy. It then proceeds to fall back to an extracted flux level of 18 Jy and continues to rise as before.

As for the other nearby sources, while they are stable prior to the sky model transient component reaching 17.5 Jy, beyond this level they suffer a very noticeable decline that continues as the transient flux is increased. It is also apparent that the other sources in the field are affected by the before-mentioned sudden local maximum of the transient light curve around a sky model flux of 25 Jy, with 3C 61.1 also showing a significant flux increase ($\sim 3\sigma$ to the scaled value).

Figure 11. The extracted flux of the transient candidate using the PySE source extractor against the manually defined flux entered into the sky model at the transient position when processing. Also shown is a measurement of the ghost source flux obtained by a forced fit at the ghost position. The input flux was defined in steps of 2.5 Jy, from 7.5 to 45 Jy. The plot also shows the extracted fluxes of four other sources in the field in order to monitor any effects to other sources, along with the solid lines which show the average flux of these field sources from the four surrounding snapshots. The error on these averages is shown by the error bar at the beginning and end of the line. Above an input flux value of 20 Jy (extracted transient flux value of 17 Jy) it becomes apparent that the other sources are beginning to be affected. They drop sharply beyond an entered flux of 30 Jy by which point the ghost source is no longer statistically significant. Note that 3C 61.1 has been scaled by subtracting 40 Jy from its flux measurements.

However, for VLSS 0110.7+8738 and VLSS 2130.1+8357, which are at a similar flux level to ILT J225347+862146, there is a hint of a decrease, although within the error bars of the flux measurements. In each case, once the sky model flux is increased to the next step, the measured fluxes return to their previous levels. When comparing the fluxes of the field sources with the corresponding averages from the four surrounding snapshots, we see that they mostly agree within all the error bars involved. The largest discrepancy comes from 3C 61.1, which appears ~ 10 per cent dimmer in the transient snapshot, which is outside the errors of the average measurement. However, the sudden increase around 25 Jy causes 3C 61.1 to match the surrounding average. This could be seen as a clue that this area represents the real flux of the transient; at this point, with 25 Jy in the sky model, the transient appears as 20 Jy in the image. Hence, with this information, we associate the true flux of the source with the point at which the ghost disappears and the other sources in the field are not heavily affected, which constrains our estimate of the flux density of ILT J225347+862146 to be in the range 15–25 Jy.

5.2.2 Testing known sources

The test detailed above was performed directly on the two field sources that were monitored during the investigation, VLSS 0110.7+8738 and VLSS 2130.1+8357, with 60-MHz flux densities of ~ 9 and ~ 15 Jy, respectively. This also included removing the sources from the calibration sky model as well as changing the input flux. Each source was treated as a separate case meaning that both were never subtracted from the sky model, or edited, at

the same time. As before, these tests were performed at the transient epoch, but also in the two neighbouring epochs to ensure that any effects were not just local to the transient-containing snapshot. Without the source in the model, the measured flux was reduced by ~ 20 per cent, with the majority of the extra flux in the field being absorbed by 3C 61.1, which appeared slightly brighter. Once the source was reinserted into the sky model, even at a low flux, the source in question returned to the expected level. However, as the sky model input flux was increased, so did the extracted flux, which is consistent with how the transient acted previously. There was also no distinguishing feature that would enable a confident definition of these sources’ ‘correct flux’ without prior knowledge. Thus, it is not a surprise that the transient flux in Section 5.2.1 is hard to identify purely from the behaviour of the source itself during calibration when altering the sky model. Ideally self-calibration would be used, but at the time of processing self-calibration with LOFAR was still a relatively untested technique.

5.2.3 Splitting the data set in time

In the test detailed above, where the transient was inserted into the sky model with various different flux values, it was noticeable that the flux that was inserted was never the flux that was measured. If the transient was not ‘on’ for the entire 11 min, this could perhaps explain why this was the case. With the transient included in the sky model at a flux of 20 Jy, the observation was first split in half and imaged; however, the flux was consistent within the 1σ error bars between each half. To probe deeper, we then referred to the 2-min images produced as part of the transient search, which did not have the transient included in the sky model. This particular observation, however, was above the average noise level (1.8 Jy beam^{-1}) with an rms of $\sim 2 \text{ Jy beam}^{-1}$. Neither the transient nor ghost source had significant detections (with the significance level now reduced to 5σ in order to try and detect the transient), and even surrounding field sources were hard to distinguish because of the poorer image quality.

In an attempt to improve the situation, using our assumption that the transient should be included in the sky model for the observation, we phase-calibrated this data set again using a larger solution interval of 1-min (previously 10 s), to allow more signal-to-noise ratio for the calculations. Using a source extraction threshold of 5σ , TRAP was able to find the transient source in the second and third of the five 2-min images: the flux densities are 20.9 (8σ) and 18.7 (7σ) Jy, respectively. The light curve can be seen in Fig. 12.

We were concerned about forcing the flux of the transient to a specific value by simply entering that value into the sky model, especially as in this case the fluxes returned were approximately equal to the flux which was entered (20 Jy). Thus, we repeated this test, but this time entering a 10-Jy transient at the position. In the 10-Jy case the transient was detected in the second image only at a lower flux density. The forced fit performed by the TRAP in the third image yields a flux measurement of 13 Jy (just below 5σ), before dropping off, which mimics the characteristics of the 20 Jy sky model case.

The first 2-min image from each test was of noticeably poorer quality than the other four 2-min images of the observation. As can be seen in Fig. 12, the forced extraction at the transient location in the first image returns the same flux density value (10 Jy) in each sky model test case. This value hints at the transient being present in this epoch as this flux level is higher than the fourth and fifth epochs, where the transient is no longer detected in both cases.

Figure 12. The extracted flux of the transient candidate in 2-min intervals, obtained using the TRAP, for the cases where the transient is included in the sky model at 10 and 20 Jy. Data points represented by a square signify that the source was extracted from the image with a blind detection. In contrast, the triangles represent flux values obtained from a forced fit at the source position, where the source was no longer above the source extraction threshold ($13 \text{ Jy}, 5\sigma$). The two light curves follow the same trend, suggesting that the transient is brighter than a 3σ limit of 7.5 Jy in the 4-min period of 04:34–04:38. The 10-Jy input case, returning a measured flux of 16 Jy , also suggests that 16 Jy may be the correct flux during this time frame. These light curves were obtained by extending the phase-calibration time interval to one min. The date of the observation was 2011 December 24.

However, due to the uncertainty in this image and the larger error bars associated with this measurement, we cannot state for certain that this is the case.

We attempted to split the data set which had been calibrated directly from the NCP field sky model, as discussed in Section 5.1.2, but the calibration was not of sufficient quality to achieve useful results.

The results here therefore suggest that the transient was brightest between the second and sixth minute of the observation, a period of four minutes. However, we are unable to fully characterize the decay, or especially the rise time of the event, and hence we cannot rule out the transient being active over a longer, 10-min time-scale.

5.3 Testing if a source can be created by the sky model

Because the transient did not correspond to any source contained in the sky model, a major concern was the possibility of ‘creating’ false sources in the field by purely inserting them into the sky model. This could explain the apparent responsiveness of the candidate to an entry in the sky model, and perhaps a source placed anywhere in the field would have the same effect, in both creating a source and causing the ghost source to disappear. We tested this in two ways. First, the snapshot containing the candidate was reprocessed with the candidate component of the sky model moved to an empty, unrelated location on the sky. This resulted in no source being ‘created’ at this location and also left the candidate, and ghost, unaffected from their original detection states.

The second test was to process the two preceding and two subsequent snapshots with the candidate component inserted into the sky model at its correct location. Previously, no detection was made of the candidate in any other snapshot, and as the data were recorded in sequence, the uv coverage of these observations were all very

similar. The result was that, once more, no source was present at the candidate location, even when placed in the sky model; this can be seen in Fig. 13, which shows the detection of the candidate along with the snapshots before and after in time.

These two results meant that simply entering sources into the sky model at an arbitrary position would not ‘create’ an artificial source. In contrast, the responsiveness of the transient candidate to such input at the correct position suggested it was a real source present in the data.

5.4 Further validity testing

A final set of tests and checks were performed to investigate whether ILT J225347+862146 was an unexpected artefact. With LOFAR being commissioned at the time, an artefact would not be completely surprising. While the telescope was in a good working state, a lack of optimization of aspects such as station calibration and beam models could cause issues. A series of tests were devised to rule out certain possible artefact causes, all performed with the source both in and out of the sky model when processing. These tests were as follows.

(i) *Broad-band RFI* – care was taken to manually reduce the data, removing anything left over that was suspected of being RFI, as well as running another pass of AOFLAGGER on the data after calibration. Neither method affected the transient source.

(ii) *Narrow-band RFI* – to rule out the possibility of narrow-band RFI, the already limited bandwidth was split into two and processed separately. The transient source remained in each half of the bandwidth, with a flux consistent within the 1σ error bars between the two halves.

(iii) *Calibrator Issues* – the calibrator observation contains nothing peculiar and was of good quality. The calibrator for this observation was 3C 295.

(iv) *Calibrator Gains Only* – previously discussed in Section 5.1.2, this test meant the phase-only calibration step using the target field sky model was skipped; instead we imaged the data set with the gain amplitude and phase solutions obtained directly from the calibrator being applied. ILT J225347+862146 was still present in the resulting image along with the ghost.

(v) *Phase Centre Shift* – the phase centre of the observation was shifted to that of the transient (a shift of ~ 4 deg). The transient was still clearly visible with the shift, especially when the source was included in the sky model.

(vi) *Equal Local Sidereal Time Observations* – 16 observations were found to have very similar local sidereal times (LST) to that of the detection measurement, so these were used to check whether the candidate was potentially caused by that particular projection of the baselines on the sky. There was no detection in any of these observations, which covered four months of recording.

(vii) *Bad Station Removal* – along with the automatic tool that was part of the initial four tests, a manual inspection of the data was also carried out, which was in agreement with the results from the tool: the same two stations were perceived as bad. After these stations were flagged, the image was generally cleaner from artefacts with the transient source unaffected.

(viii) *Random Subset of Stations* – half of the 33 stations used in the observation were randomly removed, after calibration, with the remaining data being re-imaged. This was repeated three times and the transient source continued to be present in each of three resulting maps.

(ix) *Dirty Map Check* – the source is present in the dirty map.

Figure 13. A sequence of images in time: the transient detection image along with the snapshots before and after the event, together with a zoom-in of the transient location. Importantly, each observation has been processed with the transient included in the calibration sky model, showing how even with this taken into consideration, there are no significant detections before or after the transient. These images were created using the standard imaging parameters discussed throughout the paper, including projected baselines of up to 10 km in length. The synthesized beam can be seen in the bottom-left of each image. The colour bar units are Jy beam^{-1} .

(x) *Field Subtraction* – using a sky model derived from the deeper image, the entire field apart from the transient was subtracted from the data set. The transient and ghost were clearly visible in this case, with the same flux density.

(xi) *Imaging at a different resolution* – Reducing the maximum baseline length used when imaging from 10 km to various lower values had no impact on the transient. An image using a maximum projected baseline length of 15 km was also produced in which the source was still present. However, we did not consider any images produced with projected baselines longer than 10 km scientifically useful, due to concerns regarding the quality of calibration.

(xii) *Different Imaging Weighting Schemes and Imager* – checking for further side-lobe related issues, the imaging was redone using natural and uniform weighting. The source remained in the resulting maps. The imager itself was also checked by imaging the observation with the ‘Common Astronomy Software Applications’ (CASA; McMullin et al. 2007) software rather than AWIMAGER (this meant that no PB correction was made.) and the source was still present. In this case, the candidate source was marginally brighter than the ghost: the flux densities were 5.3 and 4.5 Jy, respectively.

5.5 What is this transient?

With the candidate successfully passing the numerous exhaustive tests detailed previously, we concluded that the candidate was a real astrophysical source. Hence we proceeded to investigate its possible origin.

Table 3. Details of the follow-up observations performed with the LT.

| Obs. date | No. of epochs | Epoch exposure time (s) |
|------------|---------------|-------------------------|
| 2013/11/28 | 3 | 100 |
| 2013/12/21 | 3 | 100 |
| 2013/12/30 | 3 | 100 |
| 2014/01/12 | 2 | 300 |

5.5.1 Catalogue search and multi-wavelength follow-up

No source was found within a 2-arcmin radius of the transient position in historical radio catalogues, including VLSS, WENSS and NVSS. Also, no potential counterpart or related object was found in high-energy catalogues, and no published GRB or supernova event is known at the position.

We carried out optical follow-up of the field by using the Liverpool Telescope (LT; Steele et al. 2004), though it is worth noting that the transient was discovered two years after the event date. Therefore, while a direct counterpart would not be observed, an object of a certain type may be identified in the vicinity of the transient, and could be potentially associated with the radio emission. These observations with the LT used the r' -band filter on four different dates, which are shown in Table 3, totalling 11 epochs and 1500 s of exposure time.

The combined image, shown in Fig. 14, was calibrated against USNO-B1 (Monet et al. 2003) and reaches $r' \sim 22$ –22.5 mag. To search for a possible optical counterpart to ILT J225347+862146,

Figure 14. The resultant combined optical image obtained with follow-up observations using the LT. It reaches a depth of $r' \sim 22\text{--}22.5$ mag and is calibrated against the USNO-B1 catalogue (Monet et al. 2003). The inner circle marked on the image, centred at the reported LOFAR transient position, represents a 1σ positional error of radius 14 arcsec. The outer circle shows the 2σ positional error circle of radius 28 arcsec. The two stars which have proper motions higher than $100 \text{ mas year}^{-1}$, as indicated by the USNO-B1 (Monet et al. 2003) catalogue, are indicated by arrows.

we established an error on the positional measurement of the transient from the LOFAR data. This was calculated by accounting for the following uncertainties which contribute to the overall error: the error of the source extraction performed by the TRAP which was reported as 11 arcsec and is measured following the error analysis of Condon (1997); the average scatter of the extracted positions of bright sources in the data set by TRAP, measured to be 7 arcsec; and finally the reported 5 arcsec positional error of the VLSS catalogue, which the phase calibration sky model is based upon. Summing these values in quadrature, we gain the final positional error of 14 arcsec.

Using this value, we unambiguously detect four sources within a 2σ error circle centred at the transient position, one of which is fully enclosed by the 1σ uncertainty as shown in Fig. 14. None of these sources displayed either strong short-term (minutes) or long-term (weeks) variability. We used the USNO-B1 catalogue to look for high-proper-motion stars in the field, with the assumption that these would be nearby objects. Two of the four sources mentioned previously within the 2σ radius had associated proper motions of higher than $100 \text{ mas year}^{-1}$ and are marked in Fig. 14. However, neither of these sources exhibited a colour consistent with being an M-dwarf or any other possible transient object (but we note that the error associated with the USNO-B1 catalogue colours is significant.). In addition, both sources were detected in our LT images and no associated variability was observed. We also consulted the *Wide-Field Infrared Survey Explorer* (WISE; Wright et al. 2010) and the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006); a total of three and two sources were located within the 2σ error circle in each survey, respectively. In each case, two objects were the previously reported high-proper-motion stars; however neither of these, or the one other source in WISE, were found to be variable.

Given possible further uncertainties of the accuracy of the measured position in the LOFAR band, we extended the error circle to a radius of 1 arcmin from the transient position. A total of 20 sources were within this larger error circle in our LT observations; however, as previously, there was no strong evidence of a possible association with ILT J225347+862146.

We conclude that there is no obvious counterpart candidate. We now consider whether the radio emission could arise from either an incoherent or coherent process.

5.5.2 Incoherent origin

If we consider the incoherent emission process, we can place a limit on the maximum distance of the source by using the known characteristics of the transient along with assuming that its brightness temperature (T_B) is at the maximum $T_B = 10^{12}$ K limit, $T_{B\text{max}}$, for (un-beamed) synchrotron radiation (Kellermann & Pauliny-Toth 1969). To do this we make use of the Rayleigh–Jeans law, that is

$$T_{B\text{max}} = \frac{\Delta L_\nu}{8\pi k \nu^2 \Delta t^2}, \quad (4)$$

where ΔL_ν is the change of the luminosity in time-scale Δt , k is the Boltzmann constant and ν is the observing frequency. The luminosity at frequency ν is defined as $L_\nu = 4\pi d^2 S$, where d is the distance and S is flux density. Using this and re-arranging equation (4) we obtain an expression for the distance as follows:

$$d^2 = \frac{2k\nu^2 \Delta t^2 T_{B\text{max}}}{\Delta S}. \quad (5)$$

For the flux density change $\Delta S = 20 \text{ Jy}$ in time $\Delta t = 10 \text{ min}$, we obtain a maximum distance of 13.7 pc. This points to the possibility of the transient being a nearby flare star.

In the case where the source is relativistic, with the synchrotron radiation now beamed, the observed brightness temperature could exceed 10^{12} K. This is seen in populations such as AGN (Horiuchi et al. 2004; Kovalev et al. 2005) and GRBs (Kulkarni et al. 1999; Anderson et al. 2014). From equation (5) it can be seen that $d \propto T^{1/2}$. For example, if a brightness temperature such as 10^{16} K was observed, a value at which these sources can sometimes appear (Pietka, Fender & Keane 2015), this would place the distance estimate of the transient at 1.4 kpc, an unrealistic distance for such classes of objects.

Various previous studies have investigated the radio transient properties of flare stars at both centimetre and decametre wavelengths (Lovell 1969; Gudel et al. 1989; Bastian 1990; Jackson, Kundu & Kassim 1990; Abdul-Aziz et al. 1995; Osten et al. 2006). A recent study, Boiko et al. (2012), involved monitoring the flare stars AD Leonis ($d = 4.9 \text{ pc}$) and EV Lacertae ($d = 5.1 \text{ pc}$) with the UTR-2 telescope, located in Ukraine, during 2010 and 2011 March. These observations, performed in the frequency range of 16.5–33 MHz, yielded a total of 167 and 73 detected radio bursts from the respective stars. In the case of AD Leonis, the average flux of the bursts was in the range of 10–50 Jy, seemingly consistent with the flux measured from ILT J225347+862146 at 60 MHz. However, one discrepancy is that the average duration of these bursts seen from AD Leonis, which is 2–12 s, is considerably shorter than the apparent \sim minutes of activity observed for ILT J225347+862146. In addition, the sole detection of the transient is possibly suspicious in this context. One would expect the detection of subsequent transient events from an active flare star over a period of four months (the time-scale of this transient search). Recent results such as Notsu

et al. (2013), which show *Kepler* solar type stars exhibiting superflares, could offer an explanation, with some flare events being active for ~ 10 min time-scales (Schaefer, King & Deliyannis 2000). The flare star hypothesis could be tested further by directing future observations towards the Galactic plane rather than the NCP, as the density of flare stars should be dramatically increased.

If a flare star origin is assumed for ILT J225347+862146, along with the object not being detected in our follow-up optical image to a depth of $r' \sim 22$ mag, we can use this information to make a crude estimate of the distance of such an object such that it is consistent with a non-detection. For this, we consult a catalogue of 463 UV Cet-type flare stars compiled by Gershberg et al. (1999), selecting those which have a measured *R*-band magnitude. The stars in the catalogue have a maximum distance of 50 pc, and we also only consider M-type stars. These selected stars are then divided into two sub-type groups: early-type stars (M0-4) and late-type stars (M5-9). In total, these groups have 69 and 20 stars, respectively. We then calculated the average absolute magnitudes of these two groups, and subsequently at what average distance the population would be if the apparent magnitude became 22 mag. We found these distances to be ~ 2 kpc for the early type stars and ~ 0.3 kpc for the late type stars (consistent with estimated Galactic scale height values defined by Holwerda et al. 2014.). Hence, the object responsible for ILT J225347+862146 could be further than these distances, dependent on spectral sub-type, if it is not detected in our deep optical image obtained with the LT. However, at these distances, this would make the radio event extremely luminous, which is unlikely. Therefore, it would become likely that ILT J225347+862146 is a nearby sub-stellar object. These values could be further constrained by a deeper analysis of stellar objects, so this conclusion is made tentatively. It is also worth noting that, although we were unable to pick out a possible responsible object, it is entirely possible that the source is present in the deep optical image.

5.5.3 Coherent origin

A new class of radio transient has emerged in recent years, known as Fast Radio Bursts (FRBs). These events are single, bright (\sim Jy), bursts, which typically last for a few milliseconds and have never been seen to repeat. These bursts also exhibit high DM indicating that the population is extragalactic in origin. The first such event was seen by Lorimer et al. (2007) with the Parkes Observatory in Australia. Since this discovery, a further eight bursts have been detected using Parkes (Keane et al. 2011; Thornton et al. 2013; Burke-Spolaor & Bannister 2014; Petroff et al. 2015; Ravi, Shannon & Jameson 2015) plus one event detected with the Arecibo Observatory (Spitler et al. 2014). The implied rate of FRBs based on these events has been predicted to be up to possibly thousands of FRBs occurring every day over the entire sky (Hassall, Keane & Fender 2013; Lorimer et al. 2013). The progenitors of all these events are unknown, leading to a wide range of proposed theories regarding how FRBs are produced (see Kashiyama, Ioka & Mészáros 2013; Totani 2013; Falcke & Rezzolla 2014; Kulkarni et al. 2014; Loeb, Shvartzvald & Maoz 2014; Mottez & Zarka 2014; Zhang 2014). Searches at low frequencies have, thus far, not detected any FRBs, nor have any FRBs been found using interferometric arrays which would enable a better localization of any discovered burst (Coenen et al. 2014; Law et al. 2015).

Hassall et al. (2013) showed that when the scattering of a highly dispersed burst is significant, imaging surveys for FRBs can be competitive with pulsar-like, high-time resolution surveys, if not more

Table 4. The observed width of the four bursts reported in Thornton et al. (2013) along with the estimated width of the event at 60 MHz. To calculate the estimated width we use the relation $\tau_{\text{sc}}(\nu) \propto \nu^\gamma$ where $\gamma = -4$. Dispersion effects are ignored and we assume a scenario of the reported widths being dominated by scattering. Of the four reported bursts, FRB 110220 was the sole event to show any evidence of scattering.

| Event | Observed width at 1.3 GHz (ms) | Estimated width at 60 MHz (s) |
|------------|--------------------------------|-------------------------------|
| FRB 110220 | 5.6 | 1234 |
| FRB 110627 | <1.4 | <309 |
| FRB 110703 | <4.3 | <948 |
| FRB 120127 | <1.1 | <242 |

sensitive, in detecting such events. To investigate this possibility, we consider how the scattering time and fluence of the four FRB events reported in Thornton et al. (2013) at 1.3 GHz, compare to this event at 60 MHz. First, to achieve estimates for the scattering time of the Thornton events at 60 MHz, we use the standard relation of

$$\tau_{\text{sc}}(\nu) \propto \nu^\gamma, \quad (6)$$

where $\gamma = -4$. For the purposes of this scenario we ignore any dispersion effects and assume that the recorded burst duration is dominated by scattering. This assumption is quite reasonable when considering the value of any dispersion induced smearing of the signal, Δt_{D} , which can be calculated per MHz of bandwidth by

$$\Delta t_{\text{D}} = 8.3 \times 10^3 \text{DM} \nu_{\text{MHz}}^{-3}, \quad (7)$$

where DM is the dispersion measure and ν_{MHz} is the observing frequency in MHz. With a bandwidth of 183 kHz and an observing frequency of 60 MHz, $\Delta t_{\text{D}} = 7 \times 10^{-3}$ DMs. Thus, even with a DM value of 1000 pc cm $^{-3}$, Δt_{D} would only cause 7 s of smearing. Table 4 shows that the predicted, scatter-dominated width of the events at 60 MHz range from 242 to 1234 s (taking the upper limit values), with the highest value belonging to FRB 110220. We see that the maximum duration of our transient, ILT J225347+862146, of <660 s is quite consistent with that expected from an FRB at 60 MHz. In reality, only FRB 110220 showed any evidence of scattering.

Next we compare the fluence of the events. Taking a width of 11 min for ILT J225347+862146 (6.6×10^5 ms), and the flux as 20 Jy, the fluence of ILT J225347+862146 can be stated as $20 \times 6.6 \times 10^5 = 1.3 \times 10^7$ Jy ms at 60 MHz. Taking the shorter time-scale of four minutes (as discussed in Section 5.2.3) at 20 Jy gives a fluence of 4.8×10^6 Jy ms. The event with the highest fluence as reported in Thornton et al. (2013) was FRB 110220 with 8 Jy ms at 1.3 GHz. We can compare these fluence values assuming different spectral indices. In the case of $\alpha = 0$, a direct comparison is possible, showing that the LOFAR event has a vastly greater fluence than the known FRB. Assuming $\alpha = -2$ and extrapolating the peak flux of the LOFAR event to 1.3 GHz, the fluence now becomes 2.81×10^4 Jy ms for the 11-min scenario. This is still much greater than FRB 110220. For the LOFAR event to be consistent with this particular burst, which is by far the highest fluence of the four reported bursts in Thornton et al. (2013), then a spectral index of $\alpha \sim -4.7$ would be required. This implies that the LOFAR event would be an abnormally bright FRB, even more so than the bright Lorimer et al. (2007) burst at 30 Jy. The characteristic spectral index of FRBs is currently not well defined, but a value of -4.7 would be very steep regardless of the population. Although the time-scale of ILT J225347+862146 is consistent with a scattered FRB

at low frequencies, the required steep spectral index along with the inconsistency between the fluence of the known FRB events casts considerable doubt regarding an FRB origin. With the exact characteristics of FRBs currently unknown, we cannot state that ILT J225347+862146 belongs to the same population.

It should be noted, as described by Güdel (2002), that coherent emission from plasma processes can also occur in stellar objects such as flare stars. Such emission has also been seen from the Sun at low frequencies; for example in type III solar radio bursts (Bastian, Benz & Gary 1998). For this hypothesis, the arguments which were presented in Section 5.5.2 concerning a flare star origin also apply here. In particular, if this were the origin of ILT J225347+862146, it appears unusual to not see the event repeat over a 4-month period, yet we cannot rule out this possibility.

5.5.4 Other populations

Other populations such as AGN and X-ray binary systems were considered. However, we have insufficient evidence to confirm or rule out such classes as the origin of ILT J225347+862146.

Over the past decade, a variety of new radio transient sources have been attributed to different kinds of neutron stars. These include populations such as Rotating Radio Transients (RRATs; McLaughlin et al. 2006) and intermittent pulsars (Kramer et al. 2006), with some intermittent pulsars seen to have periods in the off-state of more than a year (Camilo et al. 2012). It is possible that the transient reported in this paper could be an atypical isolated neutron star such as these described populations; however at this time it is not possible to present any evidence to support this hypothesis.

6 TRANSIENT SURFACE DENSITY AND RATES

No transients were found at four of the five time-scales searched, with one detection in the other. This allows us to place upper limits on the rate of low-frequency transient events on the whole sky at

these time-scales. To calculate the upper limits of the surface density of transients, Poisson statistics are used, specifically:

$$P(n) = e^{-\rho A} \quad (8)$$

where ρ is the surface density of sources per square degree and A represents the equivalent solid angle obtained by multiplying the area of the sky surveyed, Ω , by the number of epochs $N - 1$. In using this approach we are also assuming isotropic probability of a transient detection, i.e. events are likely to be extragalactic in origin. We can define $P(n) = 0.05$ at the Poisson 2σ confidence level, and by rearranging equation (8) we can obtain the respective value of ρ for each time-scale, recalling that the area of sky searched in each case was 175 deg^2 . For no detections $P(0) = 0.05$ is used, whereas for the 11-min time-scale this becomes $P(1) = 0.05$ because of our single detection. These values can be found in Table 5.

ILT J225347+862146 provides us with $1_{-0.95}^{+3.74}$ transient events detected in the 11-min time-scale search, using upper and lower limits at 95 per cent confidence as defined by Gehrels (1986). As a 10σ limit was used for the source extraction, the flux density limit of this search was 7.9 Jy; moreover, 1897 11-min epochs are equivalent to 14.5 d of observations. This equates to a transient rate of $3.9_{-3.7}^{+14.7} \times 10^{-4} \text{ d}^{-1} \text{ deg}^{-2}$.

However, it should be noted that the flux density limit of this rate is defined with the assumption that sources are ‘non-ghosted’. As seen in this work, transients with an associated ghost can be reduced in brightness when not accounted for in processing. While we are yet to exactly constrain the magnitude of the effect, we can make an estimate by taking ILT J225347+862146 as an example. In this case the source was originally detected as 7.5 Jy with an accompanying ghost, and when accounted for in processing, the minimum flux estimate was 15 Jy in the 11 min image (see Section 5.2). Therefore, a minimum reduction in flux density of 50 per cent is possible, meaning that the flux density limit of the quoted rate would rise to 8 Jy for ghosted sources. For the purposes of comparing rates, in the remainder of the paper we use the ideal, non-ghosted flux density limit of 7.9 Jy.

Table 5. Summary of the transient surface densities and general information of the results of this work (top section) and other low-frequency (≤ 330 MHz) transient surveys (bottom section). We follow a similar approach to Ofek et al. (2011) where δt is the time-scale of each individual epoch searched in the survey, and Δt is the cadence time-scales(s) of the epochs observed. The value denoted by ‘-’ signifies that we were unsure of the correct value from the literature. A time value of ‘cont.’ means the observations were continuous. These values are those which are used in Figs 15 and 16.

| Survey | Telescope | ν (MHz) | Sensitivity (Jy) | ρ (deg^{-2}) | δt | Δt | No. of epochs | No. of detected transients |
|----------------------------------|-----------|----------------|------------------------|---------------------------------|------------|----------------|---------------|----------------------------|

^aReported as $1.4 \times 10^{-2} \text{ yr}^{-1} \text{ deg}^{-2}$. Using the integration time of 5 s, this converts to $2.2 \times 10^{-9} \text{ deg}^{-2}$.

^bValues for this survey are obtained from the calculations performed by Williams et al. (2013) which takes into account results from Hyman et al. (2005, 2006, 2009).

Figure 15. The logarithm of the surface density (deg^{-2}) against the logarithm of the flux density (Jy) of low-frequency transient surveys. We do not consider variable source limits. The surface densities for which transients have been detected are marked with a T . The surveys included are as follows: Hyman et al. (2005, 2006, 2009) (Hym2009); Lazio et al. (2010) (Laz2010); Jaeger et al. (2012) (Jae2012); Bell et al. (2014) (Bel2014); Obenberger et al. (2014a) (Obe2014); Carbone et al. (2015) (Car2015) and Cendes et al. (2015) (Cen2015).

6.1 Comparison to other transient surveys

We primarily consider how our results relate to other low-frequency surveys (≤ 330 MHz). We also only compare against transient surveys. Fig. 15 shows the results in which we have included all the surveys that are summarized in Table 5. In general, the results are consistent with the previous low-frequency surveys. We are able to improve upon the sensitivity of the Lazio et al. (2010) surface density by at least two orders of magnitude, with the data points from this work providing some of the most extensive searches thus far at low frequencies.

It is also possible to extrapolate our results to gigahertz frequencies, for which extensive reviews of high-frequency surveys have been compiled by Fender & Bell (2011), Ofek et al. (2011) and Fender et al. (2015). We find that our limits become competitive with previous surveys for transient populations with a spectral index of -1 , and probe deeper than previous surveys if the spectral index is steepened to -2 .

6.2 Comparison of time-dependent surface densities

It is important to realize that when comparing the transient surface density and flux densities of different surveys, the time-scale at which the survey was performed is just as important. A survey only looking at month-scale epochs will not be sensitive to minute or sub-minute-scale transients. The converse is also true depending on the survey length and sensitivity. Defining the sensitive time-scale of a transient survey is a complex task, with the epoch time (i.e. the time-scale of an individual epoch) and cadence of the epochs usually incorporating a range of values. Generally, we assume that the integration time of each observation is the time-scale of a transient on which the survey is most sensitive to detecting. If the integration time matches the duration of the transient event, then the signal-to-noise ratio will, in the majority of cases, be maximized. However as surveys are designed differently, the integration time is not always the equivalent ‘epoch time’. Some epochs are created by averaging

many different observations together for example, or other methods such as creating mosaic fields. This can be especially true in gigahertz surveys. However, the low-frequency searches presented here as a comparison mostly do have an equal integration and epoch time. This is likely due to the large FoV of some of the facilities, minimizing the need to use multiple observations to cover a large fraction of the sky.

The cadence of the observations can also be just as valid as a defining characteristic. Taking this work as an example, the NCP search is also sensitive to slow transients that could evolve on time-scales of days, up to the maximum time between two observations of four months. Thus, to avoid the complex visual that would be required to represent all this information, we compare the surveys based upon their respective epoch times (see Carbone et al. 2015 for the alternate cadence comparison). The left panel of Fig. 16 shows the same plot as in Fig. 15; however, a z -axis of time-scales has now been included to display which areas of the time-scale parameter space have been surveyed. The surveys included are the same which have previously been used and are summarized in Table 5. The right panel of Fig. 16 presents the same information but with the flux density axis collapsed, to clearly show the surface density against time-scale comparison.

What we see from this comparison is a clear definition of surface densities at the time-scales of minutes to hours within a range of sensitivities from the millijansky level to tens of jansky, which does improve upon the Lazio et al. (2010) surface density. It also becomes apparent that there is a region of sensitivities – the jansky–millijansky regime – that is yet to be explored at all time-scales. Jaeger et al. (2012) is currently the only survey to have probed to a ~ 1 mJy depth at low frequencies, and with a detected transient, this perhaps hints at the potential of further discoveries at these depths. Improving the sensitivity at shorter time-scales is also an area that could prove fruitful in transient searches.

7 CONCLUSIONS

In this paper, we have presented the results of a search for transient or variable sources at 60 MHz using the International LOFAR Telescope. The search was centred at the NCP, covering 175 deg^2 of sky with a bandwidth of 195 kHz and conducted over the period 2011 December–2012 April. The search for transients and variables was performed using the automated, newly developed, Transients Pipeline (TRAP). No transient or variable sources were discovered at time-scales of 30 s, 2 min, 55 min and 297 min. However, several candidates were discovered at the 11-min time-scale. After extensive testing to check if these objects were due to calibration or imaging errors, one of these candidates is considered to be a real astrophysical event, based on the available data. The transient, ILT J225347+862146, was seen only in one 11 min epoch out of 1897, implying a transient rate of $3.9_{-3.7}^{+14.7} \times 10^{-4} \text{ d}^{-1} \text{ deg}^{-2}$. While complicated by the processing strategy, the flux density of the event is believed to be in the range of 15–25 Jy and was most active for an estimated time of four minutes. However, the rise or decay time-scale of the event is not sufficiently well defined such that the full duration of activity could extend to a 10-min time-scale.

At present, we are unable to determine the astrophysical origin of ILT J225347+862146. There are no recorded objects at the transient position in previous radio or high-energy catalogues. Optical follow-up observations were performed at the transient position, with 20 objects detected within the 1-arcmin-radius error circle. None of these optical sources showed any short or long-term variability and no immediately obvious counterpart was identified in the field.

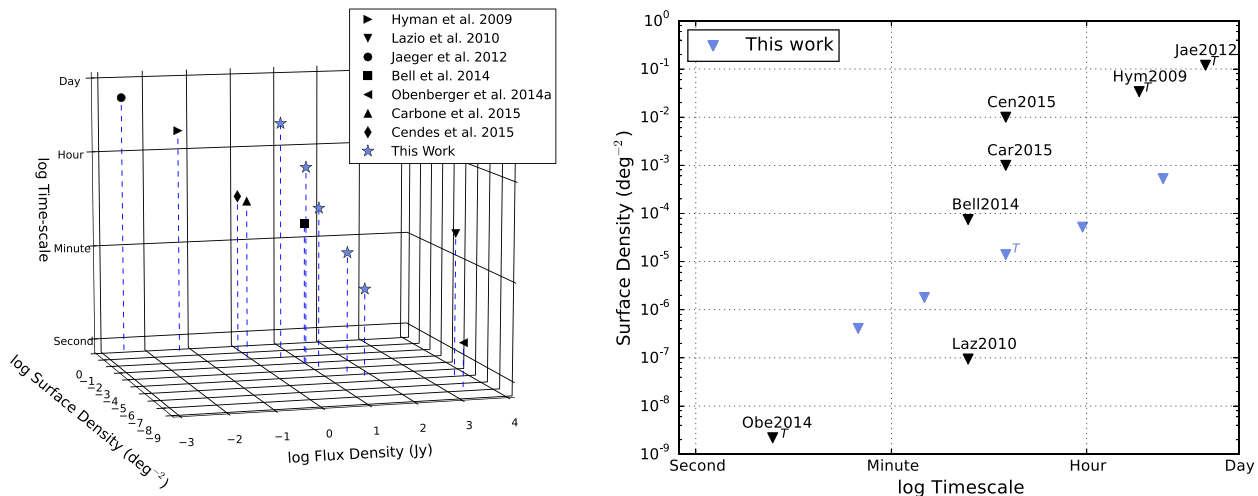

Figure 16. Left panel: a 3D plot presenting the 3D low-frequency transient search phase space when considering the time-scale of the search. Here, the logarithm of the surface density (deg^{-2}) is plotted against the logarithms of the flux density (Jy) and survey time-scale, with the latter on the z-axis. The viewing angle has been selected to primarily show the flux density and time-scale comparison. We do not consider variable source limits in this plot. The 11-min limit from this work, as well as the limits of Hyman et al. (2009), Jaeger et al. (2012) and Obenberger et al. (2014a), has been derived from the detection of one or more transients. The others are limits placed with no detections. Right panel: the same plot as the left panel, but now the flux density axis has been collapsed to clearly show the surface density and time-scale comparison. The surveys included are as follows: Hyman et al. (2005, 2006, 2009) (Hym2009); Lazio et al. (2010) (Laz2010); Jaeger et al. (2012) (Jae2012); Bell et al. (2014) (Bel2014); Obenberger et al. (2014a) (Obe2014); Carbone et al. (2015) (Car2015) and Cendes et al. (2015) (Cen2015).

However, the discovery of this transient two years after it was active diminishes the effectiveness of follow-up observations, highlighting the need for real-time transient searches and follow-up.

We considered the possibility of the transient being a flare star event due to the likely close proximity of the object. However, the time-scale of the burst is an order of magnitude longer than what would be expected from previous observations of flare stars at low frequencies. We also considered whether the event could be an FRB. While the duration of the event is consistent with a scattered burst at 1.3 GHz extrapolated to 60 MHz, it was considered unlikely due to the transient exhibiting a much larger fluence than would be expected from previously seen FRBs, which would require a very steep spectral index ($\alpha < -4.7$) to be plausible.

With LOFAR and other instruments now fully operational, the low-frequency transient sky is being probed to depths that have never previously been achieved. If the discovered transient presented in this paper is a member of a real population, then there is no question that more will be found in future and current dedicated transient surveys. This is especially true with ever improving calibration techniques and more accurate sky models at these low frequencies, combined with these surveys taking advantage of the full capabilities of these new, current generation telescopes.
