About me

Tutored at university by Dick Grimsdale, who built the world's first transistorised computer. He was himself a tutee of Alan Turing.

My second real job was coincidentally at Turing's old department, working on software for computer number 5 in the series that he had worked on.

Co-designed programming language that Python is based on.

First user on European Open Internet

Organised two workshops at the first Web conference in 1994.

Which led to W3C: I co-designed CSS, HTML, XHTML, RDFa, XForms, and others.

A typical project meeting
Discussing HTML

1957: The first municipal computer (Norwich, UK)

Just one of 21 cabinets making up the computer.
2015: The Raspberry Pi Zero

The first computer so cheap that they gave it away on the cover of a magazine

How do they compare?

The Elliot ran for about a decade, 24 hours a day.

How long do you think it would take the Raspberry Pi Zero to duplicate that amount of computing?

- 10 years?
- 1 year?
- 5 weeks?
- 5 days?
- 5 hours?
- 50 minutes?
- 5 minutes?
How do they compare?

The Elliot ran for about a decade, 24 hours a day.

How long do you think it would take the Raspberry Pi Zero to duplicate that amount of computing?

- 10 years?
- 1 year?
- 5 weeks?
- 5 days?
- 5 hours?
- 50 minutes?
- **5 minutes!**

The Raspberry Pi is about **one million** times faster...

---

Compare

The Raspberry Pi is not only one million times faster. It is also one millionth the price.

A factor of a million million.

A terabyte is a million million bytes: nowadays we talk in terms of very large numbers.

Want to guess how long a million million seconds is?

30,000 years...

A **really** big number...
Moore's Law

In fact a million million times improvement is about what you would expect from Moore’s Law over 58 years.

Except: the Raspberry Pi is two million times smaller as well, so it is much better than even that.

Let's go back to 1957

In the 50’s, computers were so expensive that nearly no one bought them, nearly everyone leased them.

To rent time on a computer then would cost you of the order of $1000 per hour: several times the annual salary of a programmer!

When you leased a computer in those days, you would get programmers for free to go with it.

Compared to the cost of a computer, a programmer was almost free.

Programming in the 50's

In the 50’s the computer’s time was expensive. A programmer would:

- write the program,
- copy it to special paper,
- give it to a typist, who would type it out,
- then give the result to another typist who would then type it out again to check it.

Why? Because it was much cheaper to let 3 people check it, than to let the computer discover the errors.
The design of programming languages

The first programming languages were designed in the 50s: Cobol, Fortran, Algol, Lisp.

They were designed with the economic relationship of computer and programmer in mind.

It was much cheaper to let the programmer spend lots of time producing a program than to let the computer do some of the work for you.

Programming languages were designed so that you tell the computer exactly what to do, in its terms, not what you want to achieve in yours.

Back to now

It happened slowly, almost unnoticed, but nowadays we have the exact opposite position:

*Compared to the cost of a programmer, a computer is almost free.*

I call this **Moore’s Switch**.
Moore's Switch

Relative costs of computers and programmers, 1957-now

But, we are still programming in programming languages that are direct descendants of the languages designed in the 1950's!

We are still telling the computers what to do.

Declarative programming

A new way of programming: declarative programming.

This describes what you want to achieve, but not how to achieve it.
XForms

XForms is a declarative system that lets you define applications.

It is a W3C standard, and in worldwide use.

- KNMI, The Dutch Weather Service
- Many Dutch (e.g. Onderwijs, Kadaster?) and UK government (e.g. Legislation) websites
- BBC
- UK NHS
- US Department of Motor Vehicles
- the British Insurance industry,
- the US Navy (in submarines),
- NASA (Jet Propulsion Laboratories),
- Verifone - a payment company, for configuring petrol pumps,
- Xerox
- Yahoo
- Remia
- EMC
- ...

Example: 150 person years becomes 10!

A certain company makes one-off BIG machines (walk in): user interface is very demanding — traditionally needed 5 years, 30 people.

With XForms this became: 1 year, 10 people.

Do the sums. Assume one person costs 100k a year. Then this has gone from a 15M cost to a 1M cost. They have saved 14 million! (And 4 years)

Example: Insurance Industry

Manager: I want you to come back to me in 2 days with estimates of how long it will take your teams to make the application.

Example: Insurance Industry

Manager: I want you to come back to me in 2 days with estimates of how long it will take your teams to make the application.

[Two days later]

Programmer: I'll need 30 days to work out how long it will take to program it.
Example: Insurance Industry

Manager: I want you to come back to me in 2 days with estimates of how long it will take your teams to make the application.

[Two days later]

Programmer: I'll need 30 days to work out how long it will take to program it.

XFormser: I've already programmed it!

Example: NHS

The British National Health Service started a project for a health records system.

- It involved 70 people
- It cost many billions of pounds.
- The hardware costs alone were £5 per patient.
- It failed.

One person then created a system using XForms.

- Hardware costs are 1p per patient.
- It runs on Raspberry Pi's.
- It is now running in 5 NHS hospitals.
XForms

XForms 1.0 was designed for online Forms.

After some experience it was realised that the design had followed HTML too slavishly, and with some slight generalisation, it could be more useful.

So was born XForms 1.1, a Turing-complete declarative programming language.

Implementations from Belgium, France, Germany, NL, UK, USA.

XForms 2.0 is in preparation.

And I am here today to tell you about it.

Form and content

Wikipedia:

"The term form refers to the work's style, techniques and media used, and how the elements of design are implemented.

Content, on the other hand, refers to a work's essence, or what is being depicted."

This is a nearly-perfect description of XForms.

XForms applications have two parts:

1. the model, describing the data, and its relationships;
2. the user interface, describing the content, and connecting to the values in the model.
State

XForms is all about state. (Which means it meshes well with REST - Representational State Transfer).

- The data can be internal or come from external sources.
- You describe the data: properties and relationships.
- You can display any selection of values in the content.

Initially the system is in a state of stasis.

When a value changes, by whatever means, the system updates related values to bring it back to stasis.

This is like spreadsheets, but much more general.

The result is: programming is much easier, since the system does all the administrative work for you.

Example

I've got a position in the world as x and y coordinates, and I want to display the map tile of that location at a certain zoom.

My data:

    x, y, zoom

Openstreetmap has a REST interface for getting such a thing:

http://openstreetmap.org/zoom/x/y.png

Map interface

However, the Openstreetmap coordinate system changes at each level of zoom.

As you zoom out, there are in each axis half as many tiles, so there are ¼ as many tiles. And the interface indexes tiles, not locations.

So to get a tile:

1. You have to know how big a tile is
2. You have to calculate the correct index using this plus the zoom.
Declarative Example

The data: x, y, zoom

\[
\begin{align*}
\text{scale} &= 2^{26} \cdot \text{zoom} \\
\text{tilex} &= \text{floor}(x/\text{scale}) \\
\text{tiley} &= \text{floor}(y/\text{scale}) \\
\text{url} &= \text{concat}("http://tile.openstreetmap.org/", \text{zoom}, ",/", \text{tilex}, ",/", \text{tiley}, ",.png")
\end{align*}
\]

That is really all that is needed (modulo syntax, which looks like this:)

\[
<\text{bind} \text{ ref="tilex" calculate="floor(../x div ../scale)"} />
\]

That's the form. Now the content:

\[
<\text{input} \text{ ref="zoom" label="zoom"} /> \\
<\text{input} \text{ ref="x" label="x"} /> \\
<\text{input} \text{ ref="y" label="y"} /> \\
<\text{output} \text{ ref="url" mediatype="image/*"} />
\]

and the tile will be updated each time any of the values change.

Live tile with zoom

![Live tile with zoom](http://tile.openstreetmap.org/10/526/336.png)
XForms, an overview

Separation of data from UI, similar to separation of style from content with CSS, with similar advantages.

Instances of data + properties.

```xml
<instance src="data.xml"/>
<bind ref="something" property="something"/>
```

Properties include:

- type
- constraints
- relevance conditions
- optional/required
- readonly/readwrite
- calculations

As you saw above in the map example, whenever a value changes, the related values are automatically updated, in spread-sheet style.
Example properties: relevant and required

```xml
<bind ref="address/state"
     required="/..\country = 'USA'"/>
```

This means that state is only required for the USA. The field will always be visible.

```xml
<bind ref="address/state"
     relevant="/..\country = 'USA'"
     required="true()"/>
```

This means that state will only be visible for the USA, but once visible will be required.

Controls in the UI then bind to data nodes, inheriting their properties.

```xml
<input ref="address/state" label="State"/>
```

Relevance

Here is an example. If you select USA as country, the control for state appears.

Street

City

Postcode

Country

Source
Similarly, the billing address is only relevant if it is different from the delivery address:

```xml
<bind ref="address[@type='Billing']"
     relevant="./@different=true()"/>
```

Delivery and billing address are the same

- **Delivery address**
  - Street
  - City
  - Country

- **Billing address**
  - Street
  - City
  - Country
Events and Actions

Typically XForms works automatically.

You can hook into the processing model to respond in special ways.

*Events* announce changes in the state; *actions* effect changes to the state.

E.g. *xforms-ready* announces that the system has initialised (and is at stasis). You could respond to this by recording today's date and time:

```xml
<action ev:event="xforms-ready">
  <setvalue ref="today" value="now()"/>
</action>
```

Events and Actions

Other events announce when a value changes, or when it changes validity, relevance, etc.

Other useful actions include setting a value, and inserting and deleting elements and attributes from data.

In fact the only way to get a vanilla button to do anything is to listen for the activation event, and then respond with an action.

```xml
<trigger label="Restart">
  <action ev:ev="DOMActivate">
    <setvalue ref="score" value="0"/>
  </action>
</trigger>
```

Content

The user-facing part is done with *controls*.

Controls are declarative too: they are designed to be device and modality independent, and describe what they do, but now how they do it, nor how they look.
Example control

For instance, the select control selects a value from a list of values. It can be implemented visually as a menu, or as radio buttons, and it can be implemented in other modalities as necessary.

```xml
<select ref="colour">
  <label>Colour:</label>
  <item><label>Red</label><value>red</value></item>
  <item><label>Yellow</label><value>yellow</value></item>
  <item><label>Green</label><value>lime</value></item>
  <item><label>Cyan</label><value>aqua</value></item>
  <item><label>Blue</label><value>blue</value></item>
  <item><label>Magenta</label><value>fuchsia</value></item>
  <item><label>Black</label><value>black</value></item>
  <item><label>White</label><value>white</value></item>
</select>
```

For instance these three are just different visual representations of this control:

**Colour:**
- Red
- Yellow
- Green
- Cyan
- Blue
- Magenta
- Black
- White

**Result**

```
Red
Yellow
Green
```
Dynamic Controls

Controls can also get their labels and content from data.

```xml
<select1 ref="colour">
  <label ref="messages/colour"/>
  <itemset ref="colours/colour">
    <label ref=".">
      <value ref="@code"/>
    </label>
  </itemset>
</select1>
```

using data like

```xml
<instance>
  <data xmlns="">
    <colours>
      <colour code="red">red</colour>
      <colour code="yellow">yellow</colour>
      <colour code="lime">green</colour>
      ...
    </colours>
    <messages>
      ...
      <colour>Colour:</colour>
      ...
    </messages>
  </data>
</instance>
```

How to

Download XSLTForms, and unpack it in a directory.

Write your XForm using this template, filling in the correct directory:

```xml
<?xml-stylesheet href="directory/xsltforms.xsl" type="text/xsl"?>
<html xmlns="http://www.w3.org/1999/xhtml"
     xmlns:ev="http://www.w3.org/2001/xml-events">
<head>
  <title></title>
  <style type="text/css">
  </style>
  <model xmlns="http://www.w3.org/2002/xforms">
    <instance>
      <data xmlns="">
      </data>
    </instance>
  </model>
</head>
<body>
  <group xmlns="http://www.w3.org/2002/xforms">
  </group>
</body>
</html>
```
