## ABSTRACT

We consider explicit methods for initial-value problems for special second-order ordinary differential equations where the righthand side does not contain the derivative of  $\mathbf{y}$  and where the solution components are known to be periodic with frequencies  $\omega_j$  lying in a given nonnegative interval  $[\underline{\omega}, \bar{\omega}]$ . The aim of the paper is to exploit this extra information and to modify a given integration method in such a way that the method parameters are "tuned" to the interval  $[\underline{\omega}, \bar{\omega}]$ . Such an approach has already been proposed by Gautschi in 1961 for linear multistep methods for first-order differential equations in which the dominant frequencies  $\omega_j$  are a priori known. In this paper, we only assume that the interval  $[\underline{\omega}, \bar{\omega}]$  is known. Two "tuning" techniques, respectively based on a least squares and a minimax approximation, are considered and applied to the *classical* explicit Störmer-Cowell methods and the recently developed *parallel* explicit Störmer-Cowell methods.

## 1. Introduction

We consider explicit methods for nonstiff initial-value problems (IVPs) for the special second-order ordinary differential equation (ODE)

$$(1.1) \quad \frac{d^2\mathbf{y}}{dt^2} = \mathbf{f}(\mathbf{y}), \quad \mathbf{y}, \mathbf{f} \in \mathbb{R}^d, \quad t_0 \leq t \leq t_{\text{end}},$$

where the righthand side does not contain the derivative of  $\mathbf{y}$ . On a set of subintervals, the solution of this IVP can be piecewise approximated by a sum of complex exponential functions like

$$(1.2) \quad \mathbf{y}(t) \approx \alpha_0 + \alpha_1 e^{i\omega_1 t} + \alpha_2 e^{i\omega_2 t} + \dots + \alpha_s e^{i\omega_s t},$$

where the vectors  $\alpha_j$  and the frequencies  $\omega_j$  are such that the approximation error is small in some sense. These frequencies  $\omega_j$  will be referred to as *dominant* frequencies. For a given subinterval and tolerance, many trigonometric approximations like (1.2) are possible, and for a given  $s$  the approximation error can be made smaller as the length of the subinterval decreases. We are particularly interested in the case where the solution of (1.1) can be approximated such that in all subintervals (i) the values of  $\|\alpha_j\|_\infty$  are of modest magnitude and (ii) the frequencies  $\omega_j$  are located in a given, relatively small, nonnegative interval  $[\underline{\omega}, \bar{\omega}]$  (in Section 2.3.1, we shall show that this is not an exceptional situation). The aim of the paper is to exploit this extra information on the solution by

modifying a given integration method for (1.1) in such a way that the method parameters are "tuned" to the interval  $[\underline{\omega}, \bar{\omega}]$ . A related approach has already been proposed by Gautschi in 1961 [2]. He considered linear multistep methods for first-order ODEs whose solutions are known to have a priori given, dominant frequencies  $\omega_j$ , and he "tuned" the linear multistep coefficients to these dominant frequencies. However, instead of assuming that the location of the dominant frequencies is given, we only assume that the interval  $[\underline{\omega}, \bar{\omega}]$  is available. By using a minimax technique, we will "tune" the coefficients of the integration method to this interval. The tuning will of course be more effective as  $\bar{\omega} - \underline{\omega}$  is smaller.

In [5] we applied the minimax approach to linear multistep methods for first-order ODEs. In this paper, we analyse this approach for two families of second-order ODE methods, viz. the *classical* explicit Störmer-Cowell methods (see e.g. [3, p.422]) and the *parallel* explicit Störmer-Cowell methods developed in [4]. In addition, we show that in general the minimax approach is superior to a tuning technique based on least squares minimization. The minimax and least squares versions of the Störmer-Cowell methods will be called *oscillatory* Störmer-Cowell methods.

## 2. The numerical schemes

The methods studied in this paper are of the explicit general linear method (GLM) form

$$(2.1) \quad \mathbf{Y}_{n+1} = (\mathbf{R} \otimes \mathbf{I}) \mathbf{Y}_n + h^2 (\mathbf{S} \otimes \mathbf{I}) \mathbf{F}(\mathbf{Y}_n), \quad n = 0, 1, \dots$$

Here  $\mathbf{R}$  and  $\mathbf{S}$  are  $k$ -by- $k$  matrices with  $k \geq 2$ ,  $\otimes$  the Kronecker product,  $h$  denotes the stepsize  $t_{n+1} - t_n$ , and each of the  $k$  components  $\mathbf{y}_{n+1,j}$  of the  $kd$ -dimensional solution vector  $\mathbf{Y}_{n+1}$  represents a numerical approximation to  $\mathbf{y}(t_n + a_j h)$ . The vector  $\mathbf{a} := (a_j)$  is called the *abscissa vector*, the quantities  $\mathbf{Y}_n$  the *stage vectors* and their components  $\mathbf{y}_{nj}$  the *stage values*. Furthermore, for any vector  $\mathbf{Y}_n = (\mathbf{y}_{nj})$ ,  $\mathbf{F}(\mathbf{Y}_n)$  contains the righthand side values  $(\mathbf{f}(\mathbf{y}_{nj}))$ . The abscissae  $a_j$  are assumed to be distinct with  $a_k = 1$ .

The GLM (2.1) is completely determined by the matrices  $\{\mathbf{R}, \mathbf{S}\}$  and the starting vector  $\mathbf{Y}_0 \approx (\mathbf{y}(t_0 + (a_j - 1)h))$ . Thus, given  $\{\mathbf{Y}_0, \mathbf{R}, \mathbf{S}\}$ , (2.1) defines the sequence of vectors  $\mathbf{Y}_1, \mathbf{Y}_2, \dots$ . Evidently, each step requires the evaluation of the  $k$  righthand side functions  $\mathbf{f}(\mathbf{y}_{nj})$ , but they can be evaluated in parallel, so that effectively the GLM requires only one righthand side function per step.

### 2.1. The local error

The local error is defined by the residue upon substitution of the exact solution into the GLM. The rate by which the residue tends to zero as  $h \rightarrow 0$  determines the *order of consistency*. We shall call the GLM (and the stage vector  $\mathbf{Y}_{n+1}$ ) *consistent of order  $q$*  if the residue upon substitution of the exact solution values  $\mathbf{y}(t_n + a_j h)$  into (2.1) is of order  $h^{q+2}$ . The value of  $q$  is often called the *stage order*. Given the vector  $\mathbf{a}$ , the consistency condition leads to a set of order conditions to be satisfied by the matrices  $\mathbf{R}$  and  $\mathbf{S}$ . In addition, in order to have convergence, the GLM has to satisfy the *necessary*

condition of *zero-stability*, that is, the matrix  $R$  should have its eigenvalues on the unit disk and the eigenvalues of modulus one should have multiplicity not greater than two.

From the consistency definition given above, the order conditions follow immediately. For simplicity of notation, we assume that the ODE is a scalar equation. Here, and in the sequel of this paper, we will use the componentwise definition of functions of vectors, that is, for any function  $g$  and vector  $\mathbf{v}$ , we define  $g(\mathbf{v}) := (g(v_j))$ . Then, substituting the exact solution into (2.1), we define the local error

$$(2.2) \quad \begin{aligned} \boldsymbol{\varepsilon}(t,h) &:= R\mathbf{Y}(t) + h^2\mathbf{S}\mathbf{F}(\mathbf{Y}(t)) - \mathbf{Y}(t+h) \\ &= \left( (R + h^2 \frac{d^2}{dt^2} S) \exp(\mathbf{b}h \frac{d}{dt}) - \exp(\mathbf{a}h \frac{d}{dt}) \right) \mathbf{y}(t) = \boldsymbol{\phi}\left(h \frac{d}{dt}\right) \mathbf{y}(t), \end{aligned}$$

where  $\mathbf{b} := \mathbf{a} - \mathbf{e}$ ,  $\mathbf{e}$  being the vector with unit entries,  $\mathbf{Y}(t)$  denotes the vector containing the exact stage values, and

$$(2.3) \quad \boldsymbol{\phi}(z) := (R + z^2S) \exp(\mathbf{b}z) - \exp(\mathbf{a}z).$$

Let us expand  $\boldsymbol{\phi}$  in the Taylor series

$$(2.4) \quad \begin{aligned} \boldsymbol{\phi}(z) &= \mathbf{c}_{-2} + \mathbf{c}_{-1}z + \dots + z^{q+2}\mathbf{c}_q + \dots, \\ \mathbf{c}_{-2} &:= R\mathbf{e} - \mathbf{e}, \quad \mathbf{c}_{-1} := R\mathbf{b} - \mathbf{a}, \quad \mathbf{c}_j := \frac{1}{(j+2)!} (R\mathbf{b}^{j+2} - \mathbf{a}^{j+2}) + \frac{1}{j!} S\mathbf{b}^j, \quad j \geq 0. \end{aligned}$$

Furthermore, let us choose the matrix  $R$  such that  $\mathbf{c}_{-2} = \mathbf{c}_{-1} = \mathbf{0}$ . By defining the matrices

$$(2.5a) \quad \begin{aligned} C &:= (\mathbf{c}_0, \dots, \mathbf{c}_{k-1}), \quad U_{\mathbf{v}} := \left( \frac{1}{2!} \mathbf{v}^2, \dots, \frac{1}{(k+1)!} \mathbf{v}^{k+1} \right), \\ X &:= \left( \mathbf{e}, \mathbf{b}, \frac{1}{2!} \mathbf{b}^2, \dots, \frac{1}{(k-1)!} \mathbf{b}^{k-1} \right), \end{aligned}$$

we find that the matrix  $S$  and the error matrix  $C$  are related by the formula

$$(2.5b) \quad SX - C = U_{\mathbf{a}} - RU_{\mathbf{b}}.$$

The conventional way of constructing IVP solvers chooses distinct abscissae  $a_j$  (so that  $X$  is nonsingular) and defines  $S$  by (2.5b) with  $C = \mathbf{0}$  yielding methods with stage order  $q = k$ . By a judicious choice of  $\mathbf{a}$  one may increase the order of accuracy at the step points  $t_n$  to obtain step point order  $p > q$  (superconvergence at the step points).

## 2.2. Störmer-Cowell methods

The definition of the classical explicit  $k$ -step Störmer-Cowell (SC) methods with (step point) order  $p = k$  can be found in e.g. [3, p. 422]. These methods fit into the GLM format (2.1) with

$$(2.6a) \quad \mathbf{a} = (2-k, 3-k, \dots, -1, 0, 1)^T, \quad R = \begin{pmatrix} \mathbf{0} & \mathbf{I} \\ 0 & \mathbf{r}^T \end{pmatrix}, \quad S = \begin{pmatrix} \mathbf{0} \\ \mathbf{s}^T \end{pmatrix}, \quad \mathbf{r} = (0, \dots, 0, -1, 2)^T,$$

where the vector  $\mathbf{s}$  is determined by substituting (2.6a) into (2.5b) and setting  $C = \mathbf{O}$ . Because the (shifted) abscissae  $b_j$  are distinct,  $X$  is invertible, and since  $\mathbf{s}^T = \mathbf{e}_k^T S$ , it follows from (2.5b) that

$$(2.6b) \quad \mathbf{s}^T = \mathbf{e}_k^T (\mathbf{U}_a - R\mathbf{U}_b) X^{-1}.$$

Note that  $\mathbf{y}_{nj} = \mathbf{y}_{n-1,j+1}$  for  $j = 1, \dots, k-1$ , so that the first  $k-1$  components  $\mathbf{f}(\mathbf{y}_{nj})$  of  $\mathbf{F}(\mathbf{Y}_n)$  are available from the preceding step. Hence, (2.6) defines a classical linear multistep type method with only one new righthand side evaluation per step.

In [4] we derived *parallel* Störmer-Cowell (PSC) methods by allowing  $S$  to be a full matrix satisfying (2.5b) with  $C = \mathbf{O}$ , and by defining  $R$  according to the (zero-stable) matrix

$$(2.7a) \quad R = (\mathbf{0}, \dots, \mathbf{0}, \mathbf{e} - \mathbf{r}, \mathbf{r}), \quad \mathbf{r} = \mathbf{e} - \frac{\mathbf{a}}{a_{k-1} - 1}$$

(note that the consistency conditions  $\mathbf{c}_{-2} = \mathbf{c}_{-1} = \mathbf{0}$  are now automatically satisfied). Since the (shifted) abscissae  $b_j$  are distinct,  $S$  can be defined by

$$(2.7b) \quad S = (\mathbf{U}_a - R\mathbf{U}_b) X^{-1},$$

to obtain PSC methods with stage order  $q = k$ . However, in [4] it was shown that the abscissa vector  $\mathbf{a}$  can be chosen such that the step point order  $p > k$ . In addition, in a few cases it is possible to choose  $\mathbf{a}$  such that instead of  $k$  computational stages only  $k-1$  computational stages are involved, that is, only  $k-1$  distinct righthand side functions, and hence only  $k-1$  processors, are needed per step. For future reference, Table 2.1 lists the abscissa vector  $\mathbf{a}$ , the number of computational stages  $k^*$  and the order  $p$ .

### 2.3. Oscillatory Störmer-Cowell methods

Suppose that the components of the exact solution  $\mathbf{y}(t)$  are expanded piecewise on subintervals with respect to the eigenfunctions  $\{\exp(\lambda t): \lambda \in \mathbb{C}\}$  of the operator  $d/dt$ . Then, it follows from (2.2) that the local error  $\mathcal{E}(t, h)$  can be expanded in the functions  $\{\phi(h\lambda)\exp(\lambda t): \lambda \in \mathbb{C}\}$ , i.e.

$$(2.2') \quad \mathcal{E}(t, h) \approx \alpha_1 \phi(h\lambda_1) e^{\lambda_1 t} + \alpha_2 \phi(h\lambda_2) e^{\lambda_2 t} + \dots + \alpha_s \phi(h\lambda_s) e^{\lambda_s t}, \quad \lambda_j \in \mathbb{C}_0,$$

where the  $\alpha_j$  are the coefficient vectors and  $\mathbb{C}_0$  denotes the set in the complex plane containing the  $s$  parameters  $\lambda_j$  needed in the expansion of the components of  $\mathbf{y}(t)$ . The expansion (2.2') shows that the magnitude of the local error can be minimized by minimizing the function  $\phi(z)$  in the domain  $h\mathbb{C}_0$ . In this paper, we consider the case where  $\mathbb{C}_0 = [i\underline{\omega}, i\overline{\omega}]$ , that is  $\mathbf{y}(t)$  can be approximated piecewise by trigonometric formulas of the form (1.2). The oscillatory Störmer-Cowell methods (briefly OSC methods) and the parallel OSC methods (POSC methods) constructed in this section use the same matrix  $R$  and the same abscissa vector  $\mathbf{a}$  as defined in (2.6a) and in {(2.7a), Table 2.1}, respectively. However, the matrix  $S$  will be chosen such that in some sense the function  $\phi(z)$  is minimized on  $[ih\underline{\omega}, ih\overline{\omega}]$ . Before discussing this minimization, we consider the piecewise trigonometric approximation of functions in more detail.

**2.3.1. Trigonometric approximations.** We start with the more general approximation problem, where we are given a function  $y$  and an approximation  $g_s$  to  $y$  satisfying  $s+1$  distinct collocation conditions  $y(\tau_m) = g_s(\tau_m)$ ,  $m = 1, \dots, s+1$ , with  $t^* \leq \tau_m \leq t^* + h$ , and where we want to know the behaviour of the approximation error  $\delta_s(t) := y(t) - g_s(t)$  in the interval  $[t^*, t^* + h]$  as  $h \rightarrow 0$ . An explicit expression for  $\delta_s(t)$  can be obtained by approximating both  $y(t)$  and  $g_s(t)$  by an  $(s+1)$ -point polynomial interpolation formula using the (distinct) points  $\tau_m$ . Although these two interpolation formulas are different, they share the same interpolating polynomial. Let  $p_{s+1}(t)$  denote this common interpolation polynomial. Then,

$$y(t) = p_{s+1}(t) + \frac{1}{(s+1)!} \pi_{s+1}(t) y^{(s+1)}(\theta_1), \quad g_s(t) = p_{s+1}(t) + \frac{1}{(s+1)!} \pi_{s+1}(t) g_s^{(s+1)}(\theta_2),$$

where  $\pi_{s+1}(t) := (t - \tau_1)(t - \tau_2) \dots (t - \tau_{s+1})$ ,  $\theta_1 = \theta_1(t)$  and  $\theta_2 = \theta_2(t)$  assume values in  $[t^*, t^* + h]$ , and  $y$  and  $g_s$  are assumed sufficiently differentiable. Subtracting these two formulas yields

$$(2.8) \quad \delta_s(t) := y(t) - g_s(t) = \frac{1}{(s+1)!} \pi_{s+1}(t) \left( y^{(s+1)}(\theta_1(t)) - g_s^{(s+1)}(\theta_2(t)) \right), \quad t^* \leq t \leq t^* + h.$$

By observing that choosing the points  $\tau_m$  equal to the zeros of the first-kind Chebyshev polynomial shifted to the subinterval  $[t^*, t^* + h]$ , that is,

$$(2.9) \quad \tau_m := t^* + \frac{1}{2} h \left( 1 + \cos \left( \frac{2m-1}{2(s+1)} \pi \right) \right), \quad m = 1, \dots, s+1,$$

minimizes the maximum of the polynomial  $\pi_{s+1}(t)$  in the interval  $[t^*, t^* + h]$ , it follows from formula (2.8) that we may expect that this choice reduces the magnitude of  $\delta_s(t)$ . It is easily verified that in the

case of the Chebyshev zeros  $\pi_{s+1}(t) = 2^{-2s-1}h^{s+1}T_{s+1}(2h^{-1}(t - t^*) - 1)$ . Thus, we have the following result:

**Theorem 2.1.** Let  $\tau_m$  be given by (2.9) and let  $g_s(t)$  be a function satisfying the collocation conditions  $y(\tau_m) = g_s(\tau_m)$ ,  $m = 1, \dots, s+1$ . If  $y$  and  $g_s$  are  $s+1$  times differentiable in  $[t^*, t^* + h]$ , then

$$y(t) = g_s(t) + \delta_s(t), \quad |\delta_s(t)| \leq \frac{h^{s+1}}{2^{2s+1}(s+1)!} |y^{(s+1)}(\theta_1) - g_s^{(s+1)}(\theta_2)|, \quad t^* \leq t \leq t^* + h,$$

where  $\theta_1$  and  $\theta_2$  are in  $[t^*, t^* + h]$ . ♦

By means of this theorem we can obtain insight into the trigonometric approximation (1.2). Let  $y(t)$  denote a component of the ODE solution  $\mathbf{y}(t)$  and let us write (1.2) for this component in the form

$$(1.2') \quad y(t) \approx g_s(t), \quad g_s(t) := \alpha_0 + \alpha_1 \cos(\omega_1 t) + \alpha_2 \sin(\omega_2 t) + \dots + \alpha_{s-1} \cos(\omega_{s-1} t) + \alpha_s \sin(\omega_s t).$$

In each subinterval  $[t_n, t_n + h]$  we require that the coefficients  $\alpha_j$  are such that  $y(\tau_m) = g_s(\tau_m)$  for the  $s+1$  points  $\tau_m$  defined by (2.9) with  $t^* = t_n$ . In this way, we obtain a piecewise trigonometric approximation of the solution component  $y(t)$ . In each subinterval, the accuracy of this approximation is determined by Theorem 2.1. This theorem implies that for any given set of frequencies  $\omega_j$  for which the linear system for the coefficients  $\alpha_j$  is nonsingular, the approximation error  $\delta(t) = O(h^{s+1})$  in each subinterval. However, large values of  $g_s^{(s+1)}(\theta_2)$  may result in large order constants. From (1.2') we see that given the frequency interval  $[\underline{\omega}, \bar{\omega}]$ , the frequencies  $\omega_j$  should be such that the magnitude of the coefficients  $\alpha_j$  is as small as possible. In order to see whether it is possible to combine coefficients of modest magnitude with frequencies in a given interval, we determined for a number of given functions, piecewise trigonometric approximations by minimizing the maximal value of  $|\delta_s(t)|$  over the  $\omega_j$  with the constraints  $\max_j \|\alpha_j\|_\infty \leq \bar{\alpha}$  and  $\underline{\omega} \leq \omega_j \leq \bar{\omega}$ . A typical situation is shown by the piecewise trigonometric approximation of the function  $y(t) = t \cos(t^2)$  on the interval  $[0,1]$ . This function oscillates with increasing frequency and amplitude. Table 2.2 lists the number of correct digits  $\Delta$  (i.e. the maximal absolute error is written as  $10^{-\Delta}$ ), the constraint on  $\alpha$ , a suitable frequency interval, and the observed order of accuracy  $p$ . Note that the order of accuracy  $p$  is in agreement with Theorem 2.1.

**Table 2.2.** Maximal approximation errors for  $y(t) = t \cos(t^2)$  on  $[0,1]$ .

$s$	$\bar{\alpha}$	$[\underline{\omega}, \bar{\omega}]$	$h = 1$	$h = \frac{1}{2}$	$h = \frac{1}{4}$	$h = \frac{1}{8}$	$h = \frac{1}{16}$	$p$

This example illustrates that the representation of oscillatory functions by means of formulas of the form (1.2) with relatively small frequency bands and modest coefficients is quite accurate.

Next, we consider the minimization of  $\phi(z)$  in the interval  $[ih\underline{\omega}, ih\overline{\omega}]$ . In the case of the SC methods only the last component of  $\phi(z)$  is relevant, so that only this component needs to be considered. In the case of the PSC methods, all components  $\phi_j(z)$  play a role and could be minimized separately on intervals  $[ih\underline{\omega}, ih\overline{\omega}]$  depending on  $j$ . However, for simplicity, we shall only consider the case where all components are minimized on the same interval  $[ih\underline{\omega}, ih\overline{\omega}]$ .

If the *location* of the frequencies  $\omega_j$  is known in advance and if there are sufficiently many free parameters available, then we obtain a perfect tuning of the method by choosing  $S$  such that the quantities  $\phi_j(ih\omega_1), \dots, \phi_j(ih\omega_s)$  vanish. This is precisely the approach of Gautschi [2] in his oscillatory linear multistep methods for first-order ODEs with a priori given frequencies.

In this paper, our starting point is that only the *interval*  $[\underline{\omega}, \overline{\omega}]$  is known. Then, the most natural option seems to be the minimization of the  $L_2$ -norm of  $\phi_j(z)$  on the interval  $[ih\underline{\omega}, ih\overline{\omega}]$ . However, we will show that the system of equations defining the matrix  $S$  becomes highly ill-conditioned if the length of the interval  $[ih\underline{\omega}, ih\overline{\omega}]$  is small. Another option (already applied in [5] in the case of linear multistep methods for first-order ODEs) chooses as many zeros of  $\phi_j(z)$  as possible in the interval  $[ih\underline{\omega}, ih\overline{\omega}]$  in such a way that the maximum norm of  $\phi_j(z)$  on the interval  $[ih\underline{\omega}, ih\overline{\omega}]$  is minimized. For a given interval  $[ih\underline{\omega}, ih\overline{\omega}]$  this minimax approach yields a system for  $S$  that is much better conditioned than in the case of the least squares approach. However, again we are faced with ill-conditioning if  $h(\overline{\omega} - \underline{\omega})$  is small. In such cases, one may decide to use a Taylor expansion of  $\phi(z)$  at the centre of the interval  $[ih\underline{\omega}, ih\overline{\omega}]$  (see Section 2.3.4).

Evidently, for  $h \rightarrow 0$ , the matrix  $S$  resulting from the least squares and minimax options converges to the matrix  $S$  defining the Störmer-Cowell type methods discussed in the preceding section. Likewise, the error matrix  $C$  defined in (2.5a) converges to  $O$ .

The least squares and minimax approach applied to Störmer-Cowell type methods will be discussed in more detail in the next subsections.

**2.3.2. The least squares approach.** The least squares approach minimizes the  $L_2$ -norm of  $\phi_j(z)$  on the interval  $[ih\underline{\omega}, ih\overline{\omega}]$ , i.e. it minimizes the components of

$$(2.10) \quad \int_{h\underline{\omega}}^{h\overline{\omega}} |\phi(ix)|^2 dx = \int_{h\underline{\omega}}^{h\overline{\omega}} \left\{ (x^2 S \cos(\mathbf{b}x) - \gamma(x))^2 + (x^2 S \sin(\mathbf{b}x) - \sigma(x))^2 \right\} dx,$$

$$\gamma(x) := R \cos(\mathbf{b}x) - \cos(\mathbf{a}x), \quad \sigma(x) := R \sin(\mathbf{b}x) - \sin(\mathbf{a}x).$$

Minimization of the components of the integral expression (2.10) yields for  $S$  the condition

$$(2.11) \quad SW = V, \quad V = (\mathbf{v}_1, \dots, \mathbf{v}_k), \quad W = (\mathbf{w}_1, \dots, \mathbf{w}_k),$$

$$\mathbf{v}_j := \int_{h\underline{\omega}}^{h\overline{\omega}} x^2 (\cos(\mathbf{b}_j x) \gamma(x) + \sin(\mathbf{b}_j x) \sigma(x)) dx,$$

$$(2.12) \quad \mathbf{w}_j := \int_{\underline{h\omega}}^{\overline{h\omega}} x^4 (\cos(b_j x) \cos(\mathbf{b}x) + \sin(b_j x) \sin(\mathbf{b}x)) dx = \int_{\underline{h\omega}}^{\overline{h\omega}} x^4 \cos((b_j \mathbf{e} - \mathbf{b})x) dx.$$

Note that  $W$  is symmetric, so that its computation requires the evaluation of only  $k(k+1)/2$  entries. For the OSC methods we only have to minimize the last component of (2.10), so that we find for  $\mathbf{s}$  the equation  $\mathbf{s}^T W = \mathbf{e}_k^T V$ . On substituting  $b_j = j-k$  it follows that the values  $\mathbf{e}_k^T \mathbf{v}_j$  can be written as

$$\mathbf{e}_k^T \mathbf{v}_j = \int_{\underline{h\omega}}^{\overline{h\omega}} x^2 \{ 2\cos(b_j x) - \cos((b_j - 1)x) - \cos((b_j + 1)x) \} dx.$$

For the POSC methods we obtain by substituting  $b_{k-1} = \frac{1}{2}$ ,  $b_k = 0$  that  $\mathbf{w}_j$  is again given by (2.12) and that

$$\mathbf{v}_j = \int_{\underline{h\omega}}^{\overline{h\omega}} x^2 \{ (\mathbf{e} - \mathbf{r}) \cos((b_j - \frac{1}{2})x) + \mathbf{r} \cos(b_j x) - \cos((b_j \mathbf{e} - \mathbf{a})x) \} dx.$$

In order to evaluate the expressions for  $\mathbf{v}_j$  and  $\mathbf{w}_j$  analytically we use the integration formulae

$$(2.13) \quad I_m := \int_{\underline{x}}^{\overline{x}} x^m \cos(cx) dx = c^{-m-1} (F_m(c\overline{x}) - F_m(c\underline{x})), \quad m = 2, 4,$$

with

$$F_2(u) = (u^2 - 2)\sin(u) + 2u \cos(u), \quad F_4(u) = (u^4 - 12u^2 + 24)\sin(u) + (4u^3 - 24u)\cos(u).$$

If  $c(\overline{x} - \underline{x})$  is small, then these formulas may be inaccurate and it is preferable to use the following expansions that are valid for  $|c\overline{x}| < 1$ :

$$(2.13') \quad I_2 = \overline{x}^3 \left( \frac{1}{3} \theta_3 - \frac{1}{5.2!} \theta_5 (c\overline{x})^2 + \frac{1}{7.4!} \theta_7 (c\overline{x})^4 - \frac{1}{9.6!} \theta_9 (c\overline{x})^6 + \frac{1}{11.8!} \theta_{11} (c\overline{x})^8 - \dots \right),$$

$$I_4 = \overline{x}^5 \left( \frac{1}{5} \theta_5 - \frac{1}{7.2!} \theta_7 (c\overline{x})^2 + \frac{1}{9.4!} \theta_9 (c\overline{x})^4 - \frac{1}{11.6!} \theta_{11} (c\overline{x})^6 + \frac{1}{13.8!} \theta_{13} (c\overline{x})^8 - \dots \right),$$

where  $\theta_j := 1 - \underline{x}^j \overline{x}^{-j}$ .

In order to compare the behaviour of the function  $\phi(z)$  associated with the least squares approach and the function  $\tilde{\phi}(z)$  associated with the conventional approach (where the components of  $\tilde{\phi}(z)$  have all their zeros at the origin), we have plotted the quotients

$$(2.14) \quad \theta_{\text{OSC}}(x) := \left| \frac{\Phi_k(i\mathbf{x})}{\tilde{\Phi}_k(i\mathbf{x})} \right|, \quad \theta_{\text{POSC}}(x) := \left\| \frac{\Phi(i\mathbf{x})}{\tilde{\Phi}(i\mathbf{x})} \right\|_{\infty},$$

as a function of  $x$ , respectively for the OSC and POSC methods. The least squares approach is more effective than the conventional approach if  $\theta(x) < 1$ . The Figures 2.1a and 2.1b respectively present

plots for the OSC and POSC methods of order  $p = 6$  on the interval  $h\underline{\omega} \leq x \leq h\bar{\omega}$  with  $h\underline{\omega} = 0.8$  and  $h\bar{\omega} = 1$  (dashed line). This behaviour of  $\theta(x)$  is typical for a whole range of  $h\underline{\omega}$  and  $h\bar{\omega}$  values, and shows that the least squares approach yields in the interval  $h\underline{\omega} \leq x \leq h\bar{\omega}$  a substantially smaller local error than the conventional approach. Note that the  $\theta(x)$  values are smaller in the SC case than in the PSC case. This is due to the fact that in the PSC case all components of  $\phi(ix)/\tilde{\phi}(ix)$  are taken into account. Furthermore, the Figures 2.2a and 2.2b show in the whole interval  $0 \leq x \leq h\bar{\omega}$  the behaviour of the functions  $\{|\phi_k(ix)|, |\tilde{\phi}_k(ix)|\}$  and  $\{\|\phi(ix)\|_\infty, \|\tilde{\phi}(ix)\|_\infty\}$ , respectively for the OSC and POSC methods (dashed and dashed-dotted lines). From these figures it follows that an underestimation of the interval of dominant frequencies is always (albeit slightly) better than the conventional approach, whereas overestimation may easily be worse than the conventional approach.

A computationally drawback of the least squares approach is the poor condition of the system defining  $S$  because  $W$  converges to a singular matrix as  $h\bar{\omega}$  becomes smaller. In fact, it follows from the definition of  $W$  and (2.13') that  $W = \frac{1}{5} (h\bar{\omega})^5 \theta_5(\mathbf{e}, \dots, \mathbf{e}) + O((h\bar{\omega})^7)$ .

**2.3.3. The minimax approach.** The condition of the system defining  $S$  can be improved by requiring that the components  $|\phi_j(ix)|$  possess zeros in the interval  $h\underline{\omega} \leq x \leq h\bar{\omega}$ . If  $|\phi_j(z)|$  would be a polynomial of degree  $2r$  in  $z$ , then its maximum norm on the interval  $[ih\underline{\omega}, ih\bar{\omega}]$  would be minimized if we identify the zeros of  $|\phi_j(z)|$  with the zeros of the corresponding minimax polynomial on  $[ih\underline{\omega}, ih\bar{\omega}]$ . Such minimax polynomials have  $r$  double zeros given by (cf. [5])

$$(2.15a) \quad z_m = ix_m, \quad x_m := \frac{1}{2} h \left( \underline{\omega} + \bar{\omega} + (\bar{\omega} - \underline{\omega}) \cos \left( \frac{2m-1}{2r} \pi \right) \right), \quad m = 1, \dots, r.$$

This leads us to require

$$(2.15b) \quad \phi(ix_m) = (R - x_m^2 S) \exp(i\mathbf{b}x_m) - \exp(i\mathbf{a}x_m) = \mathbf{0}, \quad m = 1, \dots, r,$$

where  $r$  is determined by the number of free parameters available in the function  $\phi$ . Thus, we have to solve the equations

$$(2.16a) \quad \begin{aligned} x_m^2 S \cos(\mathbf{b}x_m) &= R \cos(\mathbf{b}x_m) - \cos(\mathbf{a}x_m), \\ x_m^2 S \sin(\mathbf{b}x_m) &= R \sin(\mathbf{b}x_m) - \sin(\mathbf{a}x_m), \end{aligned} \quad m = 1, \dots, r,$$

If  $k$  is even, we may set  $r = k/2$ , so that the matrix  $S$  is completely determined by (2.16a). If  $k$  is odd, we set  $r = (k-1)/2$  and we add the consistency condition  $\mathbf{c}_0 = \mathbf{0}$ , i.e.

$$(2.16b) \quad 2S\mathbf{e} = \mathbf{a}^2 - R\mathbf{b}^2, \quad k \text{ odd.}$$

Let us introduce the  $k$ -by- $k$  matrices  $V_{\mathbf{v}}$  and  $W$ :

$$(2.17a) \quad \begin{aligned} V_{\mathbf{v}} &:= \left( -x_1^{-2} \cos(\mathbf{v}x_1), \dots, -x_r^{-2} \cos(\mathbf{v}x_r), -x_1^{-3} \sin(\mathbf{v}x_1), \dots, -x_r^{-3} \sin(\mathbf{v}x_r) \right), & k \text{ even} \\ V_{\mathbf{v}} &:= \left( \mathbf{v}^2, -x_1^{-2} \cos(\mathbf{v}x_1), \dots, -x_r^{-2} \cos(\mathbf{v}x_r), -x_1^{-3} \sin(\mathbf{v}x_1), \dots, -x_r^{-3} \sin(\mathbf{v}x_r) \right), & k \text{ odd} \\ W &:= \left( \cos(\mathbf{b}x_1), \dots, \cos(\mathbf{b}x_r), x_1^{-1} \sin(\mathbf{b}x_1), \dots, x_r^{-1} \sin(\mathbf{b}x_r) \right), & k \text{ even} \end{aligned}$$

$$W := (2\mathbf{e}, \cos(\mathbf{b}x_1), \dots, \cos(\mathbf{b}x_r), x_1^{-1}\sin(\mathbf{b}x_1), \dots, x_r^{-1}\sin(\mathbf{b}x_r)), \quad k \text{ odd.}$$

Then the conditions (2.16) can be expressed as  $SW = V := V_{\mathbf{a}} - RV_{\mathbf{b}}$ , leading to a family of OSC and POSC methods by defining

$$(2.17b) \quad S = VW^{-1}, \quad V := V_{\mathbf{a}} - RV_{\mathbf{b}}.$$

Again, the condition of the matrix  $W$  becomes worse if  $h\underline{\omega}$  and  $h\bar{\omega}$  are both small. However, the condition is much better than in the case of the least squares approach. For example, for  $k$  even we have that  $W = (\mathbf{e}, \dots, \mathbf{e}, \mathbf{b}, \dots, \mathbf{b}) + O(h^2)$ , so that only  $k/2$  columns of  $W$  are approximately equal, whereas in the least squares approach  $k$  columns of  $W$  are approximately equal.

The solid lines in the Figures 2.1 and 2.2 represent the minimax analogues of the least squares plots.

**2.3.4. Small frequency intervals.** If the zeros  $x_m$  in the minimax approach are close together, then it seems equally effective to concentrate as many zeros as possible of  $\phi$  at  $z_0 = ix_0 = ih\omega_0$  with  $\omega_0 = (\underline{\omega} + \bar{\omega})/2$ . Let us expand  $\phi(z)$  around  $z_0$  (compare (2.4))

$$(2.18) \quad \begin{aligned} \phi(z) &= \phi(z_0) + (z-z_0)\phi'(z_0) + \frac{1}{2}(z-z_0)^2\phi''(z_0) + \dots + \frac{1}{m!}(z-z_0)^m\phi^{(m)}(z_0) + \dots, \\ \phi^{(j)}(z) &= S(z^2\mathbf{b}^j + p_j z\mathbf{b}^{j-1} + q_j \mathbf{b}^{j-2}) \exp(\mathbf{b}z) + R\mathbf{b}^j \exp(\mathbf{b}z) - \mathbf{a}^j \exp(\mathbf{a}z), \quad j \geq 0, \end{aligned}$$

where  $p_{j+1} = p_j + 2$  and  $q_{j+1} = p_j + q_j$  with  $p_0 = q_0 = 0$ . If  $k$  is even, then we find

$$(2.19) \quad \begin{aligned} \operatorname{Re}\phi^{(j)}(z_0) &= S((q_j \mathbf{b}^{j-2} - x_0^2 \mathbf{b}^j) \cos(\mathbf{b}x_0) - p_j x_0 \mathbf{b}^{j-1} \sin(\mathbf{b}x_0)) + R\mathbf{b}^j \cos(\mathbf{b}x_0) - \mathbf{a}^j \cos(\mathbf{a}x_0) \\ \operatorname{Im}\phi^{(j)}(z_0) &= S(p_j x_0 \mathbf{b}^{j-1} \cos(\mathbf{b}x_0) - (x_0^2 \mathbf{b}^j - q_j \mathbf{b}^{j-2}) \sin(\mathbf{b}x_0)) + R\mathbf{b}^j \sin(\mathbf{b}x_0) - \mathbf{a}^j \sin(\mathbf{a}x_0) \end{aligned}$$

where  $j = 0, 1, \dots, (k-2)/2$ . Setting  $\operatorname{Re}\phi^{(j)}(z_0) = \operatorname{Im}\phi^{(j)}(z_0) = \mathbf{0}$  yields the required system of equations for  $S$ . If  $k$  is odd, then we add the consistency condition  $\mathbf{c}_0 = \mathbf{0}$  given by (2.16b) and proceeding as in Section 2.3.3 we can again define appropriate matrices  $V$  and  $W$  such that  $SW = V$ . The resulting matrix  $W$  is less 'singular' than in the minimax approach. In fact, if  $k$  is even, then  $W = (-\mathbf{e}, -3\mathbf{b}, q_j \mathbf{b}^{j-2}, -\mathbf{b}, 2\mathbf{e}, (p_j + q_j) \mathbf{b}^{j-1}) + O(h^2)$  where  $j = 2, 3, \dots, (k-2)/2$ , showing that for  $k > 6$  it is better conditioned than in the case (2.17a). In our numerical experiments, we define the matrix  $S$  in this way as soon as  $h(\bar{\omega} - \underline{\omega}) < 0.001$ .

**2.3.5. Oscillatory methods for arbitrary frequency intervals.** Evidently, the oscillatory methods constructed above should be more accurate than the underlying conventional methods provided that the frequency interval  $[\underline{\omega}, \bar{\omega}]$  is small. This raises the question what happens if this interval is *not* small. In other words, How robust are the oscillatory methods in nonmodel situations. To answer this question, we look at the local error of the oscillatory methods which is determined by the error matrix  $C$  defined in (2.5a). This matrix depends on  $h$  and is related to the matrix  $S$  by the equation  $C(h) = S(h)X - U_{\mathbf{a}} + RU_{\mathbf{b}}$ . We restrict our considerations to the matrix  $C(h)$  associated with the minimax method. It follows from the minimax equations (2.16a) that  $S(h)$  can be expanded in

powers of  $h^2$ , so that  $C(h)$  can also be expanded in powers of  $h^2$ . Since  $C(0) = S(0)X - U_{\mathbf{a}} + RU_{\mathbf{b}}$  vanishes, we have that  $C(h) = \frac{1}{2}h^2C''(0) + \frac{1}{24}h^4C''''(0) + O(h^6)$ . Evidently, the derivatives of  $C(h)$  equal those of  $S(h)X$ , e.g.  $C''(0) = S''(0)X$ . It is tempting to compute the derivatives of  $S(h)$  from the formula  $SW = V := V_{\mathbf{a}} - RV_{\mathbf{b}}$  by substituting Taylor expansions of  $S(h)$ ,  $V(h)$ , and  $W(h)$ . However, the resulting systems appear to be singular. For example,  $S''(0)$  satisfies the equation  $W''(0) + S''(0)W(0) = V''(0)$  in which  $W(0)$  is a singular matrix. The reason is that a number of entries of  $S''(0)$  are zero. Only if we know in advance which entries vanish, we can solve this singular system. An alternative is to look at the function  $\|\phi(ix)\|_{\infty}$  in the interval  $h\underline{\omega} \leq x \leq h\bar{\omega}$ . From (2.2') it follows

$$(2.20) \quad \begin{aligned} \|\mathcal{E}(t,h)\|_{\infty} &\leq \|\alpha_1\|_{\infty}\|\phi(ih\omega_1)\|_{\infty} + \|\alpha_2\|_{\infty}\|\phi(ih\omega_2)\|_{\infty} + \dots + \|\alpha_s\|_{\infty}\|\phi(ih\omega_s)\|_{\infty} \\ &= \alpha\left(\|\phi(ih\omega_1)\|_{\infty} + \|\phi(ih\omega_2)\|_{\infty} + \dots + \|\phi(ih\omega_s)\|_{\infty}\right), \end{aligned}$$

where  $\alpha$  is a sort of averaged weighted coefficient. Evidently,  $\alpha$  is at most  $\max_j \|\alpha_j\|_{\infty}$ , but usually much smaller. Thus, the size of  $\|\mathcal{E}(t,h)\|_{\infty}$  is largely determined by  $\|\phi(ix)\|_{\infty}$ ,  $h\underline{\omega} \leq x \leq h\bar{\omega}$ . In the following, we write  $\phi(ix)$  as  $\phi(ix, h\underline{\omega}, h\bar{\omega})$ , because both in the least squares and the minimax case, the function  $\phi(ix)$  is completely defined by  $h\underline{\omega}$  and  $h\bar{\omega}$ . It is now of interest to know how  $\phi(ix, h\underline{\omega}, h\bar{\omega})$  depends on  $h\underline{\omega}$  and  $h\bar{\omega}$ . We shall confine our considerations to the minimax case. Furthermore, since for an arbitrary problem the dominant frequencies may be located anywhere, we shall assume them in an interval  $[0, \bar{\omega}]$  where  $\bar{\omega}$  is a guess for the actual upperbound of the dominant frequencies. We expect that the quotient  $Q(x, h\bar{\omega}) := \|\phi(ix, 0, h\bar{\omega})\|_{\infty} / \|\phi(ix/h\bar{\omega}, 0, 1)\|_{\infty}$  behaves like some power of  $h\bar{\omega}$  as  $h\bar{\omega}$  tends to zero, independently of  $x$ . Therefore, we considered for a number of  $h\bar{\omega}$ -values the function  $\log Q(x, h\bar{\omega}) / \log(h\bar{\omega})$ . For  $h\bar{\omega} \leq 1$ , we found for each OSC and each POSC method an almost constant value  $k + 2$ . Hence,

$$(2.21) \quad Q(x, h\bar{\omega}) := \frac{\|\phi(ix, 0, h\bar{\omega})\|_{\infty}}{\|\phi(ix/h\bar{\omega}, 0, 1)\|_{\infty}} \approx (h\bar{\omega})^{k+2}, \quad 0 \leq x \leq h\bar{\omega} \leq 1.$$

On substitution into (2.20), we obtain

$$(2.22) \quad \|\mathcal{E}(t,h)\|_{\infty} \leq \alpha (h\bar{\omega})^{k+2} (\|\phi(i\omega_1\bar{\omega}^{-1}, 0, 1)\|_{\infty} + \|\phi(i\omega_2\bar{\omega}^{-1}, 0, 1)\|_{\infty} + \dots + \|\phi(i\omega_s\bar{\omega}^{-1}, 0, 1)\|_{\infty}).$$

This error estimate shows that irrespective the value of  $\bar{\omega}$  the oscillatory methods possess stage order at least  $q = k$  (just as the underlying conventional methods). The high power of  $\bar{\omega}$  in (2.22) looks alarming if  $\bar{\omega}$  is large. However, if the expansion (1.2) of the solution contains dominant terms of high frequency, then we need anyhow small stepsizes to represent the solution, so that it is reasonable to assume that  $h\bar{\omega} \leq 1$ . In fact, the factor  $\bar{\omega}^{k+2}$  will also appear in the first nonzero term of the Taylor expansion of the local error (see Section 2.1).

Furthermore, the error estimate (2.22) shows that the function  $\|\phi(ix, 0, 1)\|_{\infty}$ ,  $0 \leq x \leq 1$ , plays a central role. This function assumes a maximum at  $x = 1$ , so that

$$(2.23a) \quad \|\boldsymbol{\varepsilon}(t, h)\|_\infty \leq \alpha s (h\bar{\omega})^{k+2} \phi_{\max}, \quad \phi_{\max} := \|\phi(i, 0, 1)\|_\infty.$$

However, this estimate is too pessimistic, because it assumes that all dominant frequencies are located near  $\bar{\omega}$ . A more realistic estimate is obtained by replacing the sum in (2.22) by  $s$  times the averaged value of  $\|\phi(ix, 0, 1)\|_\infty$  in the interval  $0 \leq x \leq 1$ , i.e.

$$(2.23b) \quad \|\boldsymbol{\varepsilon}(t, h)\|_\infty \leq \alpha s (h\bar{\omega})^{k+2} \phi_{\text{aver}}, \quad \phi_{\text{aver}} := \int_0^1 \|\phi(i, 0, 1)\|_\infty dx.$$

Table 2.3 lists the values of  $\phi_{\max}$  and  $\phi_{\text{aver}}$  for the OSC and POSC methods. The values of  $\phi_{\text{aver}}$  are smaller than  $\phi_{\max}$  by a factor of about 10.

**Table 2.3.** Values of  $\phi_{\max}$  and  $\phi_{\text{aver}}$ .

		k = 4	k = 5	k = 6	k = 7	k = 8	k = 9	k = 10
OSC	$\phi_{\max}$	1.8 $10^{-2}$	1.6 $10^{-2}$	5.2 $10^{-3}$	4.7 $10^{-3}$	1.5 $10^{-3}$	1.4 $10^{-3}$	4.7 $10^{-4}$
	$\phi_{\text{aver}}$	2.3 $10^{-3}$	1.7 $10^{-3}$	6.7 $10^{-4}$	5.0 $10^{-4}$	1.8 $10^{-4}$	1.4 $10^{-4}$	5.1 $10^{-5}$

	$\phi_{\text{aver}}$	6.6 $10^{-4}$	2.2 $10^{-4}$	1.2 $10^{-5}$	3.5 $10^{-6}$	1.5 $10^{-6}$		

## 2.4. Stability

One may wonder how the oscillatory modes affect the stability of the method. We restrict our considerations to the *linear* stability of (2.1). The linear stability is determined by the matrix  $M(z) := R + zS$  with  $z = h^2\lambda$ ,  $\lambda$  running through the eigenvalues of the Jacobian matrix of the righthand side function  $\mathbf{f}$  of the ODE (1.1). Assuming that (1.1) is linearly stable itself, we only consider negative values of  $z$ . Here, the *stability interval* is defined by the interval  $-\beta^2 \leq z \leq 0$ , where  $M(z)$  has its eigenvalues on the unit disk. The value of  $\beta$  is called the *stability boundary*. As an illustration, we have computed the stability boundaries of the POSC methods with  $\underline{\omega} = \bar{\omega}$  and with  $\underline{\omega} = 0$ . Table 2.4 presents values of  $\beta$  for the 6th-order ( $k = 5$ ) and the 10th-order ( $k = 8$ ) POSC methods (these methods are also used in the numerical experiments in Section 3). In all cases, the oscillatory approach slightly stabilizes the PSC method until some maximal value of  $h\bar{\omega}$  is reached.

**Table 2.4a.** Stability boundaries for the case  $\underline{\omega} = \bar{\omega}$ .

$h\bar{\omega} = h\bar{\omega}$	0	0.5	1.0	1.5	2.0	2.2	2.3	3.0	3.9	4.0
POSC (6)	0.85	0.87	0.89	0.97	1.18	1.29	0			
POSC(10)	0.78	0.78	0.78	0.81	0.87	0.89	0.90	1.11	1.45	1.40

**Table 2.4b.** Stability boundaries for the case  $\underline{\omega} = 0$ .

$h\bar{\omega}$	0	0.5	1.0	2.0	4.0	6.0	8.0	10.0	11.0	12.0
POSC (6)	0.85	0.86	0.87	0.90	0.98	1.05	1.03	1.10	1.12	0
POSC(10)	0.78	0.78	0.78	0.81	0.85	0.91	0.93	0.55		

### 3. Numerical experiments

In this section we compare the performance of the OSC and POSC methods in least squares and minimax mode with the nonoscillatory Störmer-Cowell methods. In the tables of results, we use the following abbreviations:

SC(p)	Classical Störmer-Cowell method (2.6) of order $p = k$
OSC(p)	Oscillatory version of the SC(p) method
PSC(p)	Parallel Störmer-Cowell method {(2.7), Table 2.1} of order $p$
POSC(p)	Oscillatory version of the PSC(p) method.

If in the examples the exact solutions are known, the starting vector  $\mathbf{Y}_0$  was taken from the solution values ( $\mathbf{y}(t_0 + b_j h)$ ), otherwise it was computed numerically by a one-step method. We used a few well known test problems from the literature. The accuracy is defined by the number of correct digits  $\Delta$  at the end point (the maximal absolute end point error is written as  $10^{-\Delta}$ ). The number of steps taken in the integration interval is denoted by  $N$  which is at the same time for all methods the total number of *sequential* righthand sides needed to perform the integration.

#### 3.1. Problems with one dominant frequency

We start with Bessel's equation [5]

$$(3.1) \quad \frac{d^2 y}{dt^2} = - \left( 100 + \frac{1}{4t^2} \right) y, \quad y(1) = J_0(10), \quad y'(1) = \frac{1}{2} J_0(10) - 10J_1(10)$$

on the interval  $[1, 10]$  with exact solution  $y(t) = \sqrt{t} J_0(10t)$ . This equation shows that there is just one frequency  $\omega = \sqrt{100 + (4t^2)^{-1}} \approx 10$ . The oscillatory methods were applied with  $[\underline{\omega}, \bar{\omega}] = [9.9, 10.1]$ .

**Table 3.1a.**  $(N, \Delta)$  - values for the Bessel problem on  $[1, 10]$   
6th-order methods with  $[\underline{\omega}, \bar{\omega}] = [9.9, 10.1]$ .

Method	Version	100	200	400	800
SC(6)	Conventional	*	2.3	4.0	5.8
OSC(6)	Least squares	4.7	6.6	8.7	10.6
	Minimax	4.7	6.6	8.7	10.6

The second test problem is the Orbit problem from the Toronto test set [6] on the interval  $[0,20]$  with eccentricity  $\varepsilon = 0.01$ . The solution is known to have one dominant frequency  $\omega \approx 1$ . The oscillatory methods were applied with  $[\underline{\omega}, \bar{\omega}] = [0.9, 1.1]$ . The results in the Tables 3.1 and 3.2 indicate that

- (i) *The least squares approach is unreliable, even for relatively large stepsizes, which is due to the bad condition of the  $W$  matrix.*
- (ii) *The minimax approach can be used until the 20 decimals accuracy range.*
- (iii) *The minimax approach produces higher accuracies than the conventional approach.*

The fact that the minimax method is less effective in the case of the Orbit problem, particularly in the high accuracy range, can be explained by the fact that for high accuracies, frequencies other than  $\omega \approx 1$  start to come into play.

From now on, we do not apply the least squares strategy because of its erratic performance.

### 3.2. Effect of perturbing a periodic problem

In order to see how the performance of the minimax method changes if an ODE with a fully periodic solution is perturbed, we integrated the IVP

$$(3.2) \quad \begin{aligned} \frac{d^2y}{dt^2} &= -7y + 3z + \varepsilon \sin^3(y - z), & y(0) &= \frac{dy(0)}{dt} = 0, \\ \frac{d^2z}{dt^2} &= 2y - 6z + \varepsilon \cos^3(y - z), & z(0) &= \frac{dz(0)}{dt} = 1, \end{aligned} \quad 0 \leq t \leq 10.$$

If  $\varepsilon = 0$ , then the problem is fully periodic with frequencies  $\omega_1 = 2$  and  $\omega_2 = 3$ . However, if  $\varepsilon \neq 0$ , then additional frequencies are introduced. We now want to know whether the solution is still approximated piecewise by formulas of the form (1.2) with a relatively small frequency band, say  $[\underline{\omega}, \bar{\omega}] = [1.5, 3.5]$ . Table 3.3 presents results for a few values of  $\varepsilon$ . These figures show that the two OSC methods and the POSC(10) method 'feel' the introduction of additional frequencies as  $\varepsilon$  increases (the POSC(6) method seems to be insensitive). Apparently, frequencies outside the interval  $[1.5, 3.5]$  play a role. Furthermore, like the Orbit problem, these 'outside' frequencies play a more dominant role in the high accuracy range.

(iv) *The minimax approach is more effective in the lower accuracy range.*

**Table 3.3a.** Problem (3.2): (N,  $\Delta$ ) - values for 6th methods,  $[\underline{\omega}, \bar{\omega}] = [1.5, 3.5]$ .

### 3.3. Influence of wrong frequency estimates

Suppose that we apply the oscillatory methods with a wrong estimate of the frequency interval for the dominating frequencies. For example, let us compare the results for the orbit problem when integrated

with the correct, an underestimated and an overestimated frequency interval. Table 3.4 confirms our earlier conclusion (see Section 2.3.2):

- (v) *Underestimation of the interval of dominant frequencies is always better than the conventional approach, whereas overestimation may be worse.*

**Table 3.4.** Orbit problem on  $[0,20]$ :  $(N, \Delta)$  - values for various frequency intervals.

Method	Version	40	80	160	320	640
PSC(6)	Conventional	2.5	4.7	6.7	8.8	10.9

	Minimax $[0.9,1.1]$	3.4	6.2	8.1	10.1	12.2
	Minimax $[1.5,1.7]$	2.1	4.3	6.3	8.4	10.5

### 3.4. Problems with changing frequency

Next, we consider problems with a changing dominant frequency. One option is to estimate the dominant frequency in each step and to recompute the matrix  $S$ . However, this is only justified if the righthand side function is relatively expensive. If we want to integrate with a fixed  $S$ , then we should choose a sufficiently large frequency interval. We illustrate this by means of the nonlinear orbit equation of Fehlberg (cf. [1]):

$$(3.3) \quad \frac{d^2\mathbf{y}}{dt^2} = \mathbf{J} \mathbf{y}, \quad \mathbf{J} := \begin{pmatrix} -4t^2 & -\frac{2}{r(t)} \\ \frac{2}{r(t)} & -4t^2 \end{pmatrix}, \quad r(t) := \|\mathbf{y}(t)\|_2, \quad \sqrt{\pi/2} \leq t \leq 10,$$

with exact solution  $\mathbf{y}(t) = (\cos(t^2), \sin(t^2))^T$ . This problem has a constant period with respect to the variable  $t^2$ , but with respect to  $t$  the period is decreasing with  $t$ . The decreasing behaviour of the period is also clear from the equation itself. Since  $r(t) \approx 1$ , it follows from (3.3) that for large values of  $t$  the matrix  $\mathbf{J}$  behaves as a diagonal matrix with diagonal entries  $-4t^2$ . This indicates that for large  $t$ , the frequency behaves as  $2t$ . Therefore, we applied the oscillatory methods with  $[\underline{\omega}, \bar{\omega}] = [2\sqrt{\pi/2}, 20]$ . The results are presented in the Tables 3.5a and 3.5b from which we conclude:

- (vi) *Even for larger frequency bands the minimax approach outperforms the conventional approach.*

**Table 3.5a.**  $(N, \Delta)$  - values for the Fehlberg problem on  $[\sqrt{\pi/2}, 10]$  6th-order methods with  $[\underline{\omega}, \bar{\omega}] = [2\sqrt{\pi/2}, 20]$ .

POSC(10)	Minimax	5.9	9.0	12.3	15.7

### 3.5. Problems with widely spread dominant frequencies

Finally, we consider the Störmer problem in polar coordinates on the interval  $[0, 0.5]$  with  $u = \pi$  as given in [3, p. 420 (10.11a)]. Piecewise approximation of the solution by formulas of the form (1.2) leads to quite different intervals of dominant frequencies. Hence, the overall frequency band  $[\underline{\omega}, \overline{\omega}]$  will be quite large, so that we should not expect a better performance of the oscillatory methods. Surprisingly, the results in Table 3.6 show that for quite arbitrary intervals  $[\underline{\omega}, \overline{\omega}]$  the POSC methods are at least competitive with the PSC methods. Thus,

- (vii) *Even for problems whose solutions possess widely spread frequencies, the oscillatory methods do not perform worse than the conventional methods.*

**Table 3.6a.**  $(N, \Delta)$  - values for the Störmer problem on  $[0, 0.5]$  6th-order methods with various intervals  $[\underline{\omega}, \overline{\omega}]$ .
